32. Basal gastrin-like bioactivity in normal subjects and duodenal ulcer patients

R. W. HOILE, *Surgical Unit, Westminster Medical School, London*

Most reports agree that basal immunoreactive gastrin levels in normal subjects and duodenal ulcer patients are identical (McGuigan and Trudeau, 1973); these reports do not take the biological activity of the various immunoreactive gastrin molecules into account.

The use of non-quantitative bioassays and radioimmunoassays to compare normal subjects and duodenal ulcer patients has produced discrepancies suggesting the presence of a circulating gastric secretagogue in ulcer patients which appears not to be measured by radioimmunoassay (Hansky et al., 1974; Bugat et al., 1976).

A highly sensitive, quantitative, cytochemical section bioassay (Hoile and Loveridge, 1977) has been used to assess the gastrin-like activity in plasma from a group of normal subjects and a group of duodenal ulcer patients.

Blood was obtained from 24 fasting volunteers and from 15 fasting patients with proved duodenal ulceration. Heparinized plasma containing aprotinin (Trasylol) 1000 KIU/ml blood was used; this was stored at −70 °C until measurement. Synthetic human G-17-I or natural human G-17-I was used as a standard (these being equipotent in the cytochemical assay system). Each plasma was assayed at two dilutions (1 : 100 and 1 : 1000) and the mean taken for evaluation.

There was a highly significant difference between the basal plasma gastrin-like bioactivity in these two groups ($P<0·0012$).

	Gastrin-like bioactivity (pmol/l)	
Subjects	Mean (±s.d.)	Range
Normal ($n = 24$)	5·8±1·7	1·9–17·6
Duodenal ulcer ($n = 15$)	12·8±2·3	2·1–77·5

The plasma of fasting duodenal ulcer patients does contain a substance with a gastrin-like biological activity which is significantly in excess of that present in the plasma of normal volunteers.

33. Normovolaemic haemodilution in the treatment of intermittent claudication

C. J. P. YATES, ANNA BERENT, M. J. BAILEY, VIVIEN ANDREWS and J. A. DORMANDY, *Vascular Unit, St James's Hospital, London*

We attempted to improve the leg blood flow in patients unsuitable for reconstructive surgery by normovolaemic haemodilution down to a packed cell volume of 35 per cent. This technique has recently been shown to improve oxygen delivery to the brain in patients with cerebral ischaemia (Thomas et al., 1977).

Apart from full haematological and haemorheological investigations, patients' blood flow was assessed objectively by ankle pressure measurements and plethysmography before and after stress. After base line measurements, 500 ml of blood were withdrawn weekly and replaced with dextran 70 in normal saline until the packed cell volume was 35 per cent. Eight of the 11 patients reported a subjective improvement and there was no change in the other 3. On average, the peak calf blood flow during reactive hyperaemia doubled after haemodilution. As the haemoglobin concentration was only lowered by 20 per cent, there was presumably an increase in oxygen delivery.

THOMAS D. J., MARSHALL J., ROSS RUSSELL R. W. et al. (1977) Effect of haematocrit on cerebral blood flow. *Lancet* 2, 941–943.

34. A new classification for duodenitis

P. LANCE, ISOBEL FILIPE and C. WASTELL, *Department of Gastroenterology, Westminster Hospital, London*

The histopathological definition and the clinical significance of duodenitis are controversial. In an attempt to clarify these problems duodenal biopsies obtained at 75 oesophagogastroduodenoscopies (OGD) on 54 patients were examined after staining with haematoxylin and eosin (HE) for mucus glycoproteins (mucins) and for reticulin.

To assess the apparent degree of abnormality a scoring system has been devised: from 0 to 11 for the HE section; 0–5 for mucins; 0–2 for reticulin. Patients with abdominal pain but normal double contrast barium meals and normal appearance at OGD were used as a 'control' group. The average score for 45 biopsies was 2.

Five patients with active duodenal ulcers at the time of OGD had an average score of 11. The most striking features were an increase in the proportion of neutral mucins as the HE picture became more inflamed. The average score for the 5 duodenal biopsies from patients with gastric ulcers was 1. The score in those with active duodenal ulcers was different both from the control and gastric ulcer groups ($P<0\cdot001$, $P=0\cdot01$ respectively). No difference could be shown between the scores in the control group and the gastric ulcer group.

There were 7 biopsies from patients with frank duodenitis endoscopically but no ulcer craters nor abnormal double contrast barium meals; the average score was 10. This was different from the control and gastric ulcer group ($P<0\cdot001$, $P<0\cdot01$ respectively) but not from the duodenal ulcer group.

It is suggested that it is no longer adequate when studying the dyspeptic patient to restrict consideration of the duodenal mucosa to the presence or absence of a chronic ulcer crater.

35. Pelvi-ureteric junction obstruction: obstructive uropathy versus obstructive nephropathy, a new technique of assessment

H. N. WHITFIELD, K. E. BRITTON, W. F. HENDRY, C. NIMMON and J. E. A. WICKHAM, *Departments of Urology and Nuclear Medicine, St Bartholomew's Hospital, London*

One of the commonest and most difficult decisions in urology is when to operate on a kidney apparently obstructed at the pelvi-ureteric junction. We have assessed 23 patients pre- and postoperatively by three methods:

1. Diuretic radiography.
2. Direct measurement of intrarenal pelvic pressure by needle puncture (Whitaker, 1973).
3. Gamma camera renography using computerized deconvolution analysis to quantitate separately isotope transit times across the parenchyma and across the collecting system.

It was found that:

1. Diuretic urography and direct pressure measurement correlate well (Whitfield et al., 1977).
2. Of the 23 patients who were radiologically and urodynamically obstructed and who underwent surgery, 13 were renographically obstructed preoperatively in that parenchymal isotope transit time was prolonged—an obstructive nephropathy. All 9 returned to normal postoperatively. The remaining 4 patients showed normal parenchymal isotope transit time but prolonged isotope transit time through the collecting system—an obstructive uropathy.

Of the 10 cases not operated upon who were radiologically and urodynamically normal or equivocal, 3 had an obstructive nephropathy renographically. In all 3 significant deterioration in percentage renal function on the affected side has been found at follow-up.

The important practical and functional distinction between obstructive uropathy and obstructive nephropathy can be made by a non-invasive technique.

36. The duodenal brake mechanism in man

C. M. WHITE, M. R. B. KEIGHLEY and J. ALEXANDER-WILLIAMS, *Department of Surgery, General Hospital, Birmingham*

Isotonic saline empties from the stomach at the same rate after proximal gastric vagotomy and pyloroplasty as after proximal gastric vagotomy (PGV), but hypertonic dextrose empties more rapidly after PGV and pyloroplasty (Faxén et al., 1973). Therefore, the pylorus appears important in the control of emptying of hypertonic dextrose.

To determine how the pylorus controls the emptying of hypertonic dextrose, we have used a technique that continuously records the intraluminal pressures in the antrum, pylorus and duodenal bulb. We have compared the effects on gastroduodenal motility of intragastric infusion of isotonic saline (22 studies in 15 normal subjects) and of intragastric infusion of 10 per cent dextrose (10 studies in 10 normal subjects).

Compared with saline, dextrose reduced the incidence of antral contractions ($P<0\cdot02$) and increased the incidence of pyloric contractions (but not significantly, $P<0\cdot1$). Dextrose produced rhythmic, independent contractions of the pylorus in 7 of the 10 studies compared with none of the 22 during saline infusions ($P<0\cdot0001$) and produced an elevated pyloric basal pressure (5–10 cmH_2O) in 3 out of 10 compared with none out of 22 during saline infusion ($P=0\cdot02$).

During saline infusion the pylorus contracted as part of a unit comprising the whole gastroduodenal region, but during dextrose infusion it contracted independently. This independent action is probably the mechanism that controls the emptying of hypertonic dextrose and is disrupted by pyloroplasty.

FAXÉN A., DOLLEVAL G., KOCK N. G. et al. (1973) The influence of pyloroplasty on gastric emptying after parietal cell vagotomy. *Scand. J. Gastroenterol.* **8**, Suppl. 20, pp. 14–15.

37. A variant of intestinal metaplasia associated with gastric carcinoma. A premalignant lesion?

J. R. JASS and M. ISABEL FILIPE, *Department of Histopathology, Westminster Medical School, London*

Intestinal metaplasia is frequently associated with gastric carcinoma, but is also common in specimens showing only benign lesions (Morson, 1955). Intestinal metaplasia typically resembles the small intestine, though variants indistinguishable from the colon have been described. Another incomplete form with features of both gastric and intestinal epithelia has been noted (Goldman and Ming, 1968).

Gastrectomy specimens, including 35 cases of peptic ulcer and 32 of carcinoma, were investigated histologically and histochemically to demonstrate any association between carcinoma and a specific variant of intestinal metaplasia. Twenty-one cancers were bordered by severe intestinal metaplasia. In 16 this resembled colonic mucosa histochemically, showing marked sulphomucin secretion. Sulphomucins were most prominent in columnar-shaped cells in between goblet cells. Thirteen cases of peptic ulcer showed severe intestinal metaplasia, the distal antrum being the usual site of involvement. The metaplastic epithelium resembled small intestine histochemically, sialomucins predominating. Only 2 cases showed more than a trace of sulphomucin.

We consider this variant of intestinal metaplasia to be a premalignant lesion, rather than a non-specific response to carcinoma, for we have noted adenomatous polyps arising from a similar epithelium. These findings may be of use in the interpretation of gastric biopsies, possibly permitting early detection of cancer.

38. Acid phosphatase after examination of the prostate

C. D. JOHNSON, D. COSTA and J. E. CASTRO, *Departments of Urology and Chemical Pathology, Hammersmith Hospital, London*

There is a widely held belief that rectal examination of the prostate causes a rise in serum acid phosphatase. Recently this has been questioned (Shuttleworth and Blandy, 1976). We have measured serum tartrate-labile acid phosphatase (TLAP) in relation to routine rectal examination and transurethral resection of the prostate using an autoanalyser method for determining TLAP (Warren and Moss, 1977). Blood samples were first taken before and 5 min after examination, and on the first and fourth mornings afterwards.

Three groups were studied: men with benign enlargement of the prostate, 20 men with carcinoma of the prostate; 18 normal men. There was no difference in any group in TLAP before and after rectal examination. Transurethral resection of the prostate produced a rapid large rise, which had returned to normal the following morning. The assay was shown, by internal and external comparison, to be reliable and accurate.

The known instability of acid phosphatase at 37 °C in alkaline solution (Woodard, 1959) makes it probable that enzyme released into the circulation is rapidly destroyed. We have shown this to be so after transurethral resection of the prostate. Rectal examination does not raise TLAP and there is no need to delay blood sampling following this manoeuvre.

Group	Mean TLAP (i.u./l) Before	5 min after
Benign ($n = 31$)	1·0	1·0
Carcinoma ($n = 20$)	13·3	13·7
Normal ($n = 18$)	0·7	0·7

39. Psychiatric morbidity associated with adjuvant chemotherapy following mastectomy for breast cancer

A. F. COOPER, C. S. MCARDLE, AGNES R. RUSSELL and D. C. SMITH, *Departments of Psychiatry and Surgery, Victoria Infirmary, Glasgow*

Although systemic chemotherapy improves the prognosis after radical mastectomy, little information is available on the quality of survival (British Breast Group, 1976). An existing trial of adjuvant chemotherapy in stage II breast cancer provided an opportunity to examine the prevalence of psychiatric disorder in patients randomly allocated to receive chemotherapy (C), radiotherapy followed by chemotherapy (RT+C) or radiotherapy (RT) following simple mastectomy and axillary clearance.

Preliminary results from two psychiatric self-rating scales are presented: the General Health Questionnaire (GHQ) (Goldberg, 1972), which provides a non-specific measure of psychiatric morbidity, and the Leeds Self-assessment of Depression (LSD) and Anxiety (LSA) General Scales (Snaith et al., 1976). Two groups of survivors were compared at 1 year and at 18 months: group I (C and RT+C) and group II (RT). At 1 year the GHQ showed 39 per cent of group I with scores within the psychiatric illness range compared with 13 per cent of group II: at 18 months, 20 per cent of group I and none in group II. The LSD revealed 27 per cent of group I compared with 13 per cent of group II to have clinical depression at 1 year: at 18 months, 21 per cent in group I and none in group II. Groups I and II both had substantial proportions with pathological anxiety on the LSA—50 per cent and 38 per cent respectively at 1 year and 53 per cent and 25 per cent respectively at 18 months.

Comparing mean scores (Table), psychiatric morbidity, particularly depression, is significantly greater in patients completing a 1-year course of chemotherapy than in those who had radiotherapy alone; this difference is still evident at 18 months.

	GHQ	LSD	LSA
Group I ($n = 24$)			
12 mth	14·0±3·2	5·7±0·9	7·5±0·9
18 mth	9·1±3·2	3·8±0·9	8·0±1·1
Group II ($n = 15$)			
12 mth	4·3±1·6	2·5±0·7	6·6±1·1
18 mth	2·0±0·9	1·4±0·5	5·6±0·6
P I *v.* II			
12 mth	<0·01	<0·05	n.s.
18 mth	<0·05	<0·02	n.s.

40. The effect of hypoxia and hypoxic sensitizers on murine colonic tumour cultures (MAC 15)

J. P. KELLY, T. W. HANNAM and G. R. GILES, *University Department of Surgery, St James's University Hospital, Leeds*

It is likely that there are cells within solid tumours which are severely hypoxic, and it is believed that these tumour cells are radio- and chemoresistant. Agents such as metronidazole and misonidazole appear to potentiate the action of ionizing radiation on hypoxic cells and there is some suggestion that these agents may have a cytopathic action of their own which could be helpful in tumour control.

Monolayer cultures were derived from colonic tumour implants (MAC 15) carried in NMRI mice. Cell survival in cultures was measured by tritiated thymidine and leucine incorporation. Cell cultures were exposed to severe hypoxia (4 parts O_2 per thousand) for 8, 16 and 24 h and showed a pronounced fall in thymidine incorporation to 10 per cent of control levels with 24 h hypoxia, though leucine incorporation still continued at 60 per cent of normal levels. Extended hypoxia for 40 h completely suppressed growth from 3 of 6 tumours but 3 tumours contained cells which were capable of leucine incorporation at 50 per cent of the levels obtained in aerobic cultures of the same tumour. Thymidine incorporation was, however, completely suppressed.

The cytotoxic action of both metronidazole and misonidazole was tested against aerobic cultures of MAC 15 in concentrations ranging from 125 to 1000 μg/ml and found to reduce leucine and thymidine incorporation by only 10–30 per cent of control cultures. Metronidazole was tested against two hypoxic tumours in culture and found to have little cytotoxic action even at the highest doses. Misonidazole was tested against hypoxic cultures from one tumour and produced complete suppression of leucine incorporation in all doses above 125 μg/ml.

It is concluded that some tumours contain cells which can survive prolonged periods of hypoxia. These cells may be killed by misonidazole but metronidazole appears ineffective.

41. *In vitro* production of lysozyme from monocytes of breast cancer patients: a new prognostic index?

M. OLADIMEJI, M. J. B. CHARE and M. BAUM, *Department of Surgery, Welsh National School of Medicine, Cardiff*

The monocyte/macrophage series has been implicated in the host response to cancer. These cells actively secrete lysozyme so that serum levels of this enzyme may indirectly reflect the activation of the system in tumour-bearing patients. However, serum lysozyme as a prognostic marker is probably too non-specific to be of clinical value (Chare et al., 1978). It was therefore decided to assess the activity of circulating monocytes from breast cancer patients by estimating the rate of *in vitro* lysozyme production according to the method of Gordon et al. (1974). Thirty patients with various stages of breast cancer before treatment were compared with 10 age-matched controls. Two

Patient group	Mean *in vitro* lysozyme production* No.	Mean±s.d.
A Healthy controls	10	0·12±0·06
B 'Operable' breast cancer (stages I and II)	12	0·61±0·26
C Stage III breast cancer	9	1·17±0·34
D Stage IV breast cancer	9	1·30±0·59

* μg ml^{-1} 2×100^{-6} mononuclear cells 24 h^{-1}

A *v.* B, $P<0{\cdot}001$ B *v.* C, $P<0{\cdot}001$

A *v.* C, $P<0{\cdot}001$ B *v.* D, $P<0{\cdot}01$

A *v.* D, $P<0{\cdot}001$ C *v.* D, n.s.

$\times 10^6$ mononuclear cells from the peripheral blood were cultured for three sequential 24-h periods for each subject and the average rate of production of lysozyme was calculated.

There was a highly significant increase in lysozyme production from the mononuclear cells of all groups of breast cancer patients compared with controls. Furthermore *in vitro* lysozyme production was significantly greater in the more advanced cases compared with the 'operable' group.

These results suggest that the degree of 'activation' of the peripheral blood monocytes may reflect the tumour burden of the host and provide a marker of prognostic value.

42. The protective effect of jejuno-ileal bypass in experimental intestinal cancer

R. C. N. WILLIAMSON, F. L. R. BAUER, J. S. ROSS and R. A. MALT, *Department of Surgery, University of Bristol, and Harvard Medical School, Boston, Massachusetts*

Subtotal small bowel bypass for obesity might increase the risk of subsequent intestinal cancer either in the atrophic excluded segment, as in Crohn's disease (Greenstein et al., 1978), or in the hyperplastic functioning segment, as after partial enterectomy (Williamson et al., 1978). This possibility was tested in rats ($n = 100$) weighing 110–140 g and receiving 6 weekly subcutaneous injections of azoxymethane (15 mg kg^{-1} wk^{-1}), starting 1 week after operation. Animals were randomized to receive 85–90 per cent jejuno-ileal bypass or resection, or no operation (controls).

At sacrifice 36 weeks postoperatively, mean body weight after bypass was 62 per cent and after resection 80 per cent of control values ($P < 0{\cdot}001$). Adaptation following bypass or resection was manifested by 18–82 per cent increments in villus height and crypt depth in the residual functioning small bowel ($P < 0{\cdot}05$); the depth of colonic crypts was unchanged, however. There were fewer rats with intestinal tumours after bypass (36 per cent) than after either resection (80 per cent) or no operation (91 per cent) ($P < 0{\cdot}005$). Bypass reduced the mean number of colonic tumours per rat from 1·36 to 0·32 ($P < 0{\cdot}001$). Although resection did not affect colonic tumour yield, it trebled the incidence of tumours in the duodenum and jejunum ($P < 0{\cdot}02$) and caused more anastomotic tumours than bypass.

The lower tumour incidence after jejuno-ileal bypass contrasts with enhanced carcinogenesis after equivalent resection. Profound reduction in body weight appears to prevent the promotional effect of adaptive hyperplasia.

43. Randomized controlled trial of vancomycin for postoperative diarrhoea and pseudomembranous colitis

M. R. B. KEIGHLEY, Y. ARABI, D. W. BURDON, J. ALEXANDER-WILLIAMS and R. H. GEORGE, *The General Hospital, Birmingham*

Pseudomembranous colitis is caused by toxigenic strains of *Clostridium difficile* which are usually resistant to most antimicrobials except metronidazole and vancomycin (Bartlett et al., 1978). Metronidazole is rapidly absorbed, whereas vancomycin achieves high concentration in the colon and may be useful for therapy (Tedesco et al., 1978).

All patients developing diarrhoea after major intestinal operation since April 1978 have been admitted to a prospective randomized double-blind trial ($n = 44$). Patients received oral vancomycin 125 mg 6-hourly for 5 days ($n = 22$) or an identical placebo ($n = 22$). Sigmoidoscopy and rectal biopsy were performed before and 5 days after entry to the trial. Stool samples were collected on days 1, 3 and 5 for identification of toxins and *C. difficile*, and on days 2 and 4 for vancomycin assay.

Sixteen patients had toxigenic strains of *C. difficile* characteristic of pseudomembranous colitis (vancomycin, 9; placebo, 7). On the fifth day of therapy only one patient receiving vancomycin had evidence of toxins of *C. difficile* in the stool compared with six controls ($P < 0{\cdot}05$). Vancomycin completely controlled diarrhoea in all except one patient with pseudomembranous colitis compared with persistent symptoms in all except one of the controls. Vancomycin had no influence in patients without pseudomembranous colitis. In pseudomembranous colitis elimination of toxin-producing *C. difficile* from the colon by vancomycin was associated with rapid clinical improvement.

44. An electrophysiological study of the anal reflex in idiopathic faecal incontinence

M. M. HENRY, M. SWASH and A. G. PARKS, *St Mark's Hospital, London*

Histological studies have indicated that denervation of the external anal sphincter and puborectalis muscles occurs in many patients with iodipathic faecal incontinence (Parks et al., 1977). If a localized injury to the pudendal nerves is responsible then it should be possible to test this suggestion by demonstrating delayed conduction in these nerves.

We have attempted this indirectly by recording the motor-unit action potential associated with the anal reflex, of which both the sensory and motor components are conducted by the pudendal nerves (Frenckner and Van Euler, 1975). The latency and amplitude of the anal reflex was determined in a group of 33 normal subjects (aged 21–72, mean 47·7 years) comparing the results with those obtained from a group of 24 patients (aged 12–71, mean 46·5 years) with idiopathic faecal incontinence.

The results are as follows:

Reflex latency	*Range (ms)*	*Mean ± s.e. mean*	
Normal	5·0–11·25	8·3 ± 0·3	$P = 0{\cdot}001$
Incontinent	6·5–22·0	13·0 ± 0·8	(Mann–Whitney U test)

Reflex amplitude	*Range (mV)*	*Mean ± s.e. mean*	
Normal	20–350	100·9 ± 15·9	$P = 0{\cdot}001$
Incontinent	10–100	38·8 ± 5·8	(Mann–Whitney U test)

No reflex could be identified in one normal subject and the reflex was absent in 3 patients with faecal incontinence.

We consider these results provide strong evidence to support the concept that faecal incontinence in some patients results from pudendal nerve damage.

FRENCKNER B. and VAN EULER C. (1975) The influence of pudendal block on the function of the anal sphincters. *Gut* 16, 482–489.

PARKS A. G., SWASH M. and URICH H. (1977) Sphincter denervation in anorectal incontinence and rectal prolapse. *Gut* 18, 656–665.

45. Inhibition of the interdigestive myoelectric complex and lipid absorption: experimental study in the dog

P. SAVA, FABIELLE ANGEL, J. C. SCHANG and J. F. GRENIER, *Unité 61 de l'INSERM, 67200 Strasbourg, Hautepierre*

During fasting, the myoelectrical activity of the small intestine is characterized by the interdigestive myoelectric complex that recurs every 80–110 min in the dog. Feeding inhibits the myoelectric complex. The duration of inhibition of the myoelectric complex (DIMC) depends on the nature of food components (Hellemans et al., 1977). The purpose of this work was to study the variations of DIMC after ingestion of lipids associated with duodenal bypass, and to correlate them with the eventual alteration of intestinal absorption.

Six dogs were prepared with duodenal and jejunal cannulas and 3 dogs had a terminal ileostomy. Lipid at doses of 7·5 and 15 kcal/kg were alternatively given via the two cannulas. DIMC was determined from serosal jejunal electrodes. Absorption was determined by the measurement of lipid in the ileostomy output. The effect of bile (30 ml) introduced through the jejunal cannula was investigated.

Lipid	Route	DIMC (min)	Absorption (%)
7·5 kcal/kg	D	255±8	95±1
	J	211±7*	80±2*
	J+B	330±8*	100†
15 kcal/kg	D	447±7	75±2
	J	256±6*	50±3*
	J+B	450±7	70±3

D, duodenal; J, jejunal; J+B, jejunal +bile.
All results are mean±s.e. mean.
* Values significantly different from D.
† In each experience.

These results demonstrate that a defect of lipid absorption is associated with significant reduction of DIMC. Return of DIMC and the percentage absorption towards normal values was obtained by the addition of bile. These results suggest that a close relationship between DIMC and intestinal absorption of lipid might exist.

HELLEMANS J., VANTRAPPEN G., EECKHOUT C. et al. (1977) Inhibition of the interdigestive myoelectric complex in dogs by commercial food, proteins, carbohydrates, fat and MCT. *Gastroenterology* **72**, 1160.

46. Faecal bile acids and clostridia in the aetiology of colorectal cancer

W. R. MURRAY, ANN BLACKWOOD, K. C. CALMAN and C. MACKAY, *University Departments of Oncology and Surgery, Western Infirmary, Glasgow*

Hill et al. (1975) have reported an increased bile-acid concentration in association with nuclear dehydrogenating clostridia (NDC) in the faeces of colorectal cancer patients. This finding has not been confirmed and its importance in the aetiology of colorectal cancer remains unclear. We have studied 34 patients with colorectal cancer and 28 control patients with no known gastrointestinal disease. Stool specimens were obtained for biochemical analysis (total faecal bile acid, lithocholic acid, deoxycholic acid and cholic acid) and NDC isolation. A dietary history was taken from 30 colorectal cancer patients.

The mean total faecal bile-acid concentration (μmol/g) in the control group was 20±11 (mean±s.d.), significantly higher ($P<0·001$) than in the colorectal cancer group. No statistically significant difference was found between the two groups in either the concentration or the percentage distribution of the individual faecal bile acids measured. NDC were isolated from 69 per cent of colorectal cancer patients and 44 per cent of control patients, this difference not reaching statistical significance. Dietary history analysis failed to reveal significant increases in fat or protein intake in the colorectal cancer patients.

These results do not support the findings of Hill et al. and indicate that any relationship between faecal bile acids, bacteria and colorectal cancer requires further evaluation.

HILL M. J., DRASAR B. S., WILLIAMS R. E. O. et al. (1975) Faecal bile acids and clostridia in patients with cancer of the large bowel. *Lancet* **1**, 535–539.

47. Re-examination of the amylase to creatinine clearance ratio (ACCR) in acute pancreatitis

C. W. IMRIE, F. C. CAMPBELL, D. A. GORDON, A. J. MCKAY and J. O'NEILL, *Department of Surgery, Royal Infirmary, Glasgow*

It has been suggested that the ACCR is both a reliable and simple index of the presence of acute pancreatitis (Murray and Mackay, 1977) and that the test has a high degree of specificity for this disease (Warshaw and Fuller, 1975). Quite recently certain doubts have been expressed about these claims, and the place of the test in the diagnosis of acute pancreatitis (Lankisch et al., 1977). The present study comprised 86 patients with primary acute pancreatitis (mean admission serum amylase 5900 U/l). Whether an ACCR of 3 per cent or 5·3 per cent is considered the upper limit of normal, a significant proportion of results were in the normal range for day 1 through to day 5 of illness (Table). Indeed, of the 12 patients with the highest serum amylase values, a mean ACCR of 4·6 per cent was found on the first day of illness and 7 of these had an ACCR of less than 3 per cent. Comparison with other parameters revealed significantly fewer diagnostic levels of ACCR than serum or urine amylase alone, or the ratio of urinary amylase to urinary creatinine on day 1, and no advantage for ACCR as a test later in the illness. Both the specificity and reliability of this test must be seriously questioned.

'Normal' ACCR results (%)

	Day 1	2	3	4	5
ACCR					
<3%	41	53	49	35	50
<5·3%	66	82	76	81	91

48. The effect of gastric distension on the canine gastric basal electrical rhythm (BER)

J. M. SYMES, M. HUTTON, E. A. PEARCE, N. REVERDIN and D. L. WINGATE, *Department of Gastrointestinal Science, The London Hospital*

Slowing of the frequency of the gastric basal electrical rhythm (BER) before and after vagotomy has been observed during gastric distension (Nelson et al., 1967; Kelly and Code, 1969). The effect of gastric distension on the BER was analysed on 13 isolated canine stomach preparations. Distension produced an immediate change of the BER rate, which returned to the fasting level after emptying of the stomach. In 73 studies a decrease in the frequency occurred in 67 per cent, an increase in 27 per cent and no change in 6 per cent.

Secondly, the response of the gastric BER to distension was measured on three conscious dogs before (12 studies) and after (12 studies) truncal vagotomy. Whereas both liquid and solid meals caused a similar immediate slowing of the BER rate of 20 per cent, recovery to the fasting level within 30 min was only seen after the liquid meals. Although less pronounced the gastric response to distension was preserved after vagotomy in two animals. In the third animal (with gastric retention) the BER remained irregular throughout fasting and feeding.

It is concluded that (*a*) although the isolated preparations suggest a local muscle response, the direction of the response may be dictated by extrinsic nerves; (*b*) persistence of the response after vagotomy suggests a neural controlling mechanism independent of the central vagus.

49. Experimental studies of small-diameter arterial prostheses

A. A. B. BARROS D'SA, L. R. SAUVAGE, M. W. WALKER, K. BERGER, S. B. ROBEL and S. G. YATES, *Royal Victoria Hospital and*

Reconstructive Cardiovascular Research Center International, Providence Medical Center, and the Department of Surgery, School of Medicine, University of Washington, Seattle, Washington

A total of 150 graft experiments has been performed in the canine carotid artery to compare the 5–6-hour thrombotic threshold velocity (TTV), the flow surface index (FSI) and the 1-week patency rates of prostheses 6 cm long and 3–4 mm in diameter of different materials and wall configurations. Prostheses studied were crimped and non-crimped porous Dacrón fabric (USCI Sauvage filamentous vascular prosthesis), expanded polytetrafluoroethylene (Gore-Tex) and glutaraldehyde-processed human umbilical vein (Meadox Biograft). These studies show important differences among these grafts (Table).

Graft	TTV (cm/s)	FSI 5–6 h	FSI 1 wk	1-wk patency
USCI Sauvage non-crimped	5–6	99	98	83%
Gore-Tex	5–6	85	98	80%
USCI Sauvage crimped	6–6·5	75	98	62·5%
Meadox Biograft	12–15	5	38	60%

These implantations in the canine carotid artery indicate that a properly pre-clotted, non-crimped, porous fabric prosthesis (autogenous fibrin flow surface) is substantially better than the Meadow Biograft. In contrast, the Gore-Tex prosthesis is comparable to a properly pre-clotted, non-crimped, porous fabric Dacron prosthesis.

On this basis, a non-crimped porous fabric Dacron prosthesis that has both the surgical advantages of crimping and the rheologic attributes of a smooth flow surface has been developed.

50. Postoperative changes in red blood cell deformability

M. J. BAILEY, A. DODDS, C. J. P. YATES and J. A. DORMANDY, *Vascular Unit, St James's Hospital, London*

Red blood cell deformability is known to influence blood flow through the microcirculation and may also be important in determining flow rates through larger vessels. Red cell deformability has been shown to be impaired in patients with peripheral vascular disease (Reid et al., 1976) and patients with diabetes (Barnes et al., 1977).

To measure red blood cell deformability, we have modified our earlier filtration technique and used a 5 per cent concentration of erythrocytes resuspended in their own plasma, which is then passed through a nucleopore filter with pore size of 5 μm diameter.

We have shown that patients undergoing major reconstructive surgery have a fall in red cell deformability to 50 per cent of preoperative values. This fall is maximal at 24–48 h and returns to preoperative values after 5–10 days. We have investigated the cause of this change by studying deformability in patients undergoing non-arterial operations without blood transfusion and in patients having operations under general anaesthetic but minimal surgical stress (cystoscopy). Patients having non-urgent transfusion for anaemia were also studied, and measurements were made in 30 patients in all. The only patients in whom deformability changed were those subject to surgical stress. We believe that this postoperative change may contribute to early failures of arterial surgery, and may predispose to deep vein thrombosis.

51. Porcine dermis therapy for varicose ulcers

J. S. H. RUNDLE, C. V. RUCKLEY, A. A. GUNN, SHEILA CAMERON, PATRICIA WILSON, NAN WATSON and R. A. ELTON, *Departments of General Surgery and Physiotherapy, Western General Hospital, Edinburgh, and Bangour General Hospital, West Lothian*

A pilot study suggested that lyophilized partial-thickness pigskin dressings (Corethium II, Ethicon Ltd) could accelerate the healing of varicose and traumatic leg ulcers (Rundle et al., 1976).

A clinical trial was undertaken to compare this material with 'Bisgaard' therapy as standardized in our hospital in recent years using paste-impregnated bandages (Seton Products Ltd), elastic compression and physiotherapy. Twenty-six ambulant outpatients were randomly allocated to treatment or control groups. Patients with multiple ulcers received only one form of treatment.

	Bisgaard ($n = 11$)	Porcine ($n = 15$)
Age (yr)	56–80 (mean 70·6)	45–88 (mean 64·1)
No. of ulcers	17	22
Surface area (cm^2)	0·47–16·43 (mean 3·83)	23–47·85 (mean 8·01)
Duration of healing	3–63 wk (mean 13·1)	1–16 wk (mean 7·0)

In 3 patients (1 Bisgaard, 20 porcine) the ulcers failed to heal and they required inpatient treatment. Comparison of healing rates showed a mean for the Bisgaard treated ulcers of 7·7 weeks per $\sqrt{(\text{area})}$ versus 4·7 weeks for the porcine group. The improvement in healing rate was statistically significant.

RUNDLE J. S. H., CAMERON S. H. and RUCKLEY C. V. (1976) New porcine dressing for varicose and traumatic leg ulcers. *Br. Med. J.* **2**, 216.

52. Assessment of treatment in Raynaud's phenomenon by Doppler ultrasound velocimetry

M. J. G. O'REILLY, G. TALPOS, V. C. ROBERTS and L. T. COTTON, *Department of Biomedical Engineering, King's College Hospital Medical School, London*

Little information is available about the state of digital vessel patency in patients with Raynaud's phenomenon unless arteriography, with its potential hazards, has been performed. Now, using a safer method—directional Doppler velocimetry—vessel patency can be estimated along the length of the finger. Digital vessel systolic pressure can also be measured accurately by inflating a plastic cuff, placed around the proximal phalange, above systolic pressure, and then listening to the returning arterial flow, on cuff deflation, with a Doppler probe.

Twenty-six patients with Raynaud's phenomenon were randomly allocated to 3 treatment groups—placebo, systemic heparinization (5000 i.u. i.v.) once weekly for 4 weeks and plasmapheresis once weekly for 4 weeks. The total weekly plasma exchange was 2·5 l. Digital vessel patency and pressures were assessed before treatment, after treatment and at 6-month follow-up. Assessment was performed at 20±0·5 °C and after hand immersion in water at 15 °C and 45 °C.

Plasmapheresis produced a significant ($P<0·05$) improvement in vessel patency and in digital blood pressure ($P<0·02$) at 20±0·5 °C and at 15 °C as assessed by Doppler techniques. Whole blood viscosity, at high shear rates (91 s^{-1}) was significantly reduced ($P<0·01$) in the plasmapheresis group, but in no other.

Thus, plasmapheresis is an effective form of treatment in severe Raynaud's phenomenon.

53. Evaluation of a pulsed Doppler imaging system in peripheral vascular disease

D. R. BIRD, R. J. LUSBY, A. E. B. GIDDINGS, R. SKIDMORE, J. P. WOODCOCK and R. N. BAIRD, *Departments of Surgery and Medical Physics, Bristol Royal Infirmary*

A directional 30-channel 5 MHz pulsed Doppler artery and vein imaging system (MAVIS, GEC Medical) was used to detect (*a*) progressive narrowing in synthetic arterial grafts and (*b*) stenosis at the origin of the profunda femoris artery. Longitudinal and transverse vessel images were obtained: in addition, each of the 30 channels was selected in turn to obtain the velocity wave forms and hence the velocity profile of the moving stream of blood. The channel with the maximum velocity wave form was recorded above and below arterial stenoses to demonstrate loss of pulsatility and wave form damping.

In a follow-up study of patent 10-mm Dacron grafts, 128 scans of 32 limbs were performed. The ultrasound images of these grafts were satisfactory and reproducible. The internal diameter of long iliopopliteal grafts did not change from groin to mid-thigh level, but decreased from 7·84±0·36 mm (mean ±s.e. mean) at mid-thigh level to 6·31±0·44 mm at popliteal level, indicating distal graft stenosis ($P<0{\cdot}005$, Wilcoxon). Damping of the maximum velocity time wave form was also demonstrated in these long grafts. No distal narrowing was found in 14 short grafts (10 aortofemoral, 4 iliofemoral), but in 3 the femoral anastomosis was dilated. In 3 grafts localized but haemodynamically insignificant stenoses were detected.

Mapping of blood flow at the bifurcation of the common femoral artery was performed in 14 patients with chronic ischaemia. The vessel images compared poorly with arteriograms, but severe damping of the maximum velocity time wave forms across the profunda femoris ostium was demonstrated, indicating the presence of haemodynamically significant profunda orifice stenosis (damping factor>1·57).

These results suggest that the anatomical and functional information obtained with MAVIS can together be used in the non-invasive detection of luminal narrowing of Dacron arterial grafts and in the preoperative assessment of arterial disease.

54. The relationship between ultrasonic pulsatility index and proximal arterial stenosis

W. E. BARRIE, D. H. EVANS and P. R. F. BELL, *Department of Surgery, Leicester General Hospital*

Although the pulsatility index (PI), derived from spectral analysis of ultrasonic Doppler signals, is claimed to assess accurately arterial inflow (Gosling, 1972; Charlesworth et al., 1975), the relationship between proximal arterial stenosis and PI has not been fully evaluated.

In a series of canine experiments over 200 measurements of pressure, flow (using an indwelling electromagnetic flowmeter) and PI were made distal to implanted arterial stenoses of varying length (5–9 mm) and cross-sectional area (36–94 per cent reduction in area). These measurements indicate:

1. The PI correlates broadly with severity of stenosis but for individual stenoses the scatter was wide.
2. For stenoses of up to 75 per cent reduction in area the PI varied between 1 and 7; only when the stenosis was greater than 90 per cent was the PI invariably low (between 0·25 and 2).
3. For a given stenosis the PI correlated with peripheral resistance. The dependence of the PI on peripheral resistance was much greater for stenoses of less than 75 per cent reduction in area than for the tighter stenoses.

It seems that the PI is influenced both by inflow and by the resistance of the vessels distal to the stenosis. In this canine model, the PI could not predict the adequacy of arterial inflow.

55. The influence of aortofemoral Dacron bypass grafts on platelet and fibrinogen kinetics

C. N. MCCOLLUM, S. M. RAJAH, M. D. PEPPER, P. A. LEAROYD and R. C. KESTER, *University Department of Surgery, St James's University Hospital, and Regional Blood Transfusion Centre, Leeds*

Occlusion of an arterial graft results partly from the thrombogenic effects of its luminal surface. Dacron aortofemoral grafts rarely thrombose because of wide graft diameter and rapid blood flow, but results in small grafts are less satisfactory so that antithrombotic therapy may be indicated. The duration of such therapy should be based on the 'thrombogenic period' in graft maturation.

To evaluate this period, platelet and fibrinogen kinetics, using ^{51}Cr and ^{125}I respectively, were measured preoperatively and at 3, 6 and 9 months in 10 patients after aortofemoral Dacron bypass. Six age-matched volunteers were similarly studied.

	Control	Preop.	3 mth	6 mth	9 mth
Platelet survival (d)	8·5	8·8	7·6	7·9	8·4
Platelet turnover ($\times 10^3$/d)	34	39	47	39	30
Fibrinogen $T_{\frac{1}{2}}$ (d)	4·1	3·7	3·4	4·0	4·0
Fibrinogen fractional catabolic rate	0·26	0·27	0·35	0·29	0·27

Platelet survival time was reduced ($P<0{\cdot}01$) and platelet turnover increased at 3 months postoperatively compared with preoperative levels. Similarly, fibrinogen $T_{\frac{1}{2}}$ was decreased, and fractional catabolic rate increased at 3 months ($P<0{\cdot}01$). These indices of thrombogenic activity returned to preoperative levels by 9 months. Preoperative platelet and fibrinogen consumption in patients tended to be higher than in volunteers.

We suggest that Dacron aortofemoral grafts remain thrombogenically active for about 9 months. Where blood flow conditions are suboptimal or graft diameters are small, it may be prudent to use antithrombotic therapy to protect patency.

56. Anti-thrombotic therapy for vascular prostheses: an experimental model evaluating aspirin and dipyridamole

C. N. MCCOLLUM, M. J. CROW, S. M. RAJAH and R. C. KESTER, *University Department of Surgery, St James's University Hospital, and Regional Blood Transfusion Centre, Leeds*

Although Dacron is widely used in the construction of arterial prostheses, the fabric has been shown to be relatively thrombogenic (Hamlin et al., 1978). We have investigated the effect of acetysalicylic acid (ASA), dipyridamole (DPM) and combinations of these drugs on the response of platelets to woven Dacron perfused in an artificial circulation.

These circuits were perfused by heparinized blood donated by 6 volunteers after each had taken: (1) no drugs; (2) ASA 300 mg t.d.s., (3) DPM 100 mg q.i.d., (4) ASA 300 mg+DPM 75 mg combined t.d.s.; (5) ASA 80 mg+DPM 75 mg combined t.d.s., separately for 1 week (each treatment separated by 2 weeks). Bleeding times were performed before each donation. Platelet count, adhesion and aggregation were estimated through perfusion. Each graft's surface was examined by scanning electron microscopy at the end of perfusion.

	Mean reduction during perfusion P. c. (%)	P. ag. (%)	P. ad. (%)	Mean no. platelets adherent to Dacron	Mean bleeding time (min)
1	17·2	16·9	11·3	251	5·15
2	8·1*	−2·1*	7·5	73*	10·6*
3	15·8	3·9	7·66*	145*	6·2
4	11·8	−12·6*	0·33*	72*	11*
5	7·7*	−10·5*	6·5*	80*	7·6*

P.c., platelet count; P. ag., platelet aggregation; P. ad., platelet adhesion.
* $P<0{\cdot}05$ compared with control (group 1) value (Wilcoxon signed rank test).

ASA was more effective than DPM, significantly impairing function and reducing consumption of platelets by Dacron, but prolonging the bleeding time. Inhibition of platelet function and platelet adherence to Dacron by low dose ASA+DPM was similar to that achieved by ASA alone and larger dose ASA+DPM, the bleeding time being less extended. We suggest that ASA in low dose plus DPM may favourably influence the thrombogenic response of flowing blood to Dacron with less risk of bleeding.

HAMLIN G. W., RAJAH S. M., CROW M. J. et al. (1978) Evaluation of the thrombogenic potential of three types of arterial graft. *Br. J. Surg.* **65**, 272–276.

57. Suppressor cells in immunological enhancement

W. S. HENDRY and N. L. TILNEY, *Departments of Surgery, Aberdeen University and Harvard University (Peter Bent Brigham)*

The survival of (LEW×BN) F_1 cardiac allografts can be significantly prolonged in LEW hosts by combining active and passive enhancement (Tilney et al., 1978). The role of suppressor cells in immunological enhancement was tested *in vivo*, transferring thymus cells from enhanced rats bearing well-functioning grafts to syngeneic recipients of test cardiac allografts. Six days after transplantation, 10^8 thymocytes were transferred to virgin LEW rats given a (LEW×BN) F_1 cardiac allograft 24 h later. The mean survival time of test grafts was 14±3 days and 6·4±1 days following transfer from enhanced and unmodified LEW hosts respectively ($P<0\cdot001$). The transfer of 10^6, 10^7 and 5×10^8 thymocytes from enhanced rats 6 days post transplant gave test graft survival of 8±1·5 days, 7·5±0·5 days and 8±1 days respectively (n.s.).

When 10^8 thymocytes were harvested from enhanced hosts 3, 9 or 12 days post transplant, test allograft mean survival times were 7·4±1 days, 9±1 days ($P<0\cdot005$) and 7·4±0·5 days, respectively. Specificity was tested by the survival of third party allografts. Following transfer of 10^8 thymocytes 6 days post transplant, the mean survival time (LEW×Wi Fu) F_1 allografts was 7±1 days (n.s.). Passive transfer of serum from enhanced animals 6 days post transplant did not prolong test graft survival (mean survival time = 7·5±1 days).

Suppressor cells participate in the maintenance of enhancement, the phenomenon being highly specific and time- and dose-restricted.

TILNEY N. L., BANCEWICZ J., ROWINSKI W. et al. (1978) Enhancement of cardiac allografts in rats. Comparison of host responses to different treatment protocols. *Transplantation* **25**, 1–6.

58. The effect of immunization and route of administration on the anti-tumour action of pig mononuclear cells

TERESA LAI and SARAH PRICHARD-THOMAS, *Department of Surgery, University of Bristol*

Cells from pig mesenteric lymph nodes were used to treat mouse mammary tumours. Two models were employed.

In the first 1×10^5 tumour cells were injected intravenously on day 0 into isogenic mice to produce pulmonary tumours. The mice received 200 rad thoracic irradiation on day 3 and 20×10^6 pig mononuclear cells on day 7. The pig cells were either non-immune or tumour-immune. They were injected intravenously to make contact with the tumours in the lung. Only immune (I) pig cells, injected intravenously, reduced the number of pulmonary tumour nodules on day 14.

Category	Median no. of pulmonary tumours	Significance Un.	Significance Irr.	
Untreated ($n=6$)	20·0		n.s.	
Irradiation ($n=12$)	14·0	n.s.		
Irradiation+non-I cells i.v. ($n=4$)	23·5	n.s.	n.s.	
Irradiation+I cells i.v. ($n=8$)	5·5	<0·001	<0·02	$P<0\cdot005$
Irradiation+I cells i.p. ($n=8$)	15·0	n.s.	n.s.	

Un,, untreated; Irr,, irradiated.

In the second model 1×10^6 tumour cells were injected intraperitoneally on day 0 to produce multiple peritoneal tumours in isogenic mice. Pig mononuclear cells, 40×10^6 non-immune or tumour-immune, were injected on day 7. Only immune pig cells injected intraperitoneally were effective in prolonging the survival of the mice.

Category	Mean survival time (d)	Significance*	
Untreated ($n=7$)	29·9		
Non-I pig cells i.p. ($n=7$)	33·0	n.s.	
I pig cells i.p. ($n=8$)	44·6	$P<0\cdot02$	$P<0\cdot05$
I pig cells i.v. ($n=7$)	31·0	n.s.	

* Significance from untreated.

Thus, to obtain an anti-tumour effect, pig cells must be tumour-immune and make contact with the tumours.

59. Prolongation of murine skin allografts across a major histoincompatibility locus using supernatants from Concanavalin-A-activated spleen cells

P. J. GUILLOU, B. BUSH and G. R. GILES, *University Department of Surgery, St James's University Hospital, Leeds*

Supernatants from Concanavalin-A (Con-A)-activated spleen cell cultures (CONS) have been found to suppress the responses of laboratory mice to challenge with heterologous erythrocytes (Reinertsen and Steinberg, 1977). This may possibly be mediated by the stimulation of suppressor T-lymphocytes (Tadakuma and Pierce, 1978). We therefore decided to explore the possibility that CONS might delay the rejection of allografts across a major histoincompatibility locus. CONS and control supernatants were prepared from 48-h cultures of BALB/c splenocytes. Con-A was removed from all the supernatants with Sephadex G-75. Three groups of BALB/c mice were injected intraperitoneally with 1 ml twice daily for 5 days with either CONS, control supernatant or isotonic saline. Skin grafts from donor C3H mice were performed on all the injected mice either on the day of first injection (day 0) or 24 h after the first injection (day −1). Using standard criteria the day upon which graft rejection occurred was determined. The results were as follows:

	Mean day of rejection (±s.d.)
Control supernatants ($n=11$)	10·5±1·25
Saline ($n=23$)	11·1±1 3
CONS ($n=23$)	14 6±1·8

The mean time of rejection following injection of CONS was significantly longer than both that of the saline control group ($t=7\cdot6$, $P<0\cdot001$) and the control supernatant group ($t=6\cdot27$, $P<0\cdot001$). Further analysis of these results reveals that skin grafts in animals whose injections of CONS commenced on day 0 ($n=11$) survived 15·4±1 9 days whereas those whose injections commenced on day −1 ($n=12$) survived 13·8±1·3 days, though this just failed to reach statistical significance ($r=99\cdot2$).

It is concluded that supernatants from Con-A-activated spleen cells do contain a factor which can defer allograft rejection.

60. The predictive value of pre-transplant mixed lymphocyte reaction in renal transplantation: a prospective 5-year study

B. K. SHENTON, G. PROUD and R. M. R. TAYLOR, *Department of Surgery, Royal Victoria Infirmary, Newcastle upon Tyne*

A correlation between the outcome of cadaver kidney transplants and the strength of stimulation obtained between recipient and donor cells in the two-way mixed lymphocyte reaction has been described (Opelz and Terasaki, 1977). However, the conventional 5-day test is not suitable for prospective matching in cadaver transplantation. The aim of the present investigation was to evaluate donor×recipient mixed lymphocyte reaction prospectively in a series of 72 consecutive renal transplants (from January 1971 to November 1972) using a 3-h *in vitro* technique. Graft survival was assessed independently at 5 years. Mixed lymphocyte reactions were measured in the macrophage electrophoretic mobility (MEM) test (Shenton et al., 1975). Two groups were considered, based on the recommendation of Cochrum et al. (1973): (*a*) stimulation indices (SI) up to 8 per cent; and (*b*) SIs above 8 per cent.

Actuarial graft survivals for all patients are shown in the Table, which gives the percentage graft survival.

	SI	
	0–8% ($n = 33$)	8 1–16·1% ($n = 27$)
0·5 yr	91	63 4
1 yr	75·5	50·7
2 yr	75·5	38
3 yr	65	38
4 yr	59	34·5
5 yr	59	21·6

Five-year graft survival was significantly greater ($P<0\ 01$) in the low (<8 per cent) SI group. Prior blood transfusion combined with an SI of less than 8 per cent gave the best graft survival (80 per cent at 6 years).

In conclusion, low SIs are associated with better 5-year graft survival (59 per cent) than high SIs (21·6 per cent). The assessment of the mixed lymphocyte reactions in the MEM test may allow more precise selection of recipients for transplantation and the test described is of clinical relevance since it may be completed in 3 h.

61. Timing of blood transfusions before organ transplantation

G. PROUD, B. K. SHENTON, P. S. VEITCH and R. M. R. TAYLOR, *University Department of Surgery, Royal Victoria Infirmary, Newcastle upon Tyne*

The benefits of previous blood transfusions on kidney transplant survival are becoming increasingly recognized. However, it is unknown if the timing of the transfusions is important. This was studied in the inbred rat cardiac allograft model using the following unrelated strains: (i) heart donor, PVG/C (AgB5); (ii) blood donor, DA (AgB4); (iii) recipient, WAG (AgB2). Two 2-ml transfusions of DA whole blood were given to the recipient 3 days apart either 2 weeks (2/52) or 4 weeks (4/52) before transplantation. The experiment was repeated adding immunosuppression (IS) to the transfusion regimen—azathioprine 4 mg kg^{-1} d^{-1} and prednisolone 6 mg kg^{-1} d^{-1}, given intraperitoneally, commencing 1 h before transplantation.

Experimental groups	*n*	Median graft survival (d)
A Untreated control rats	17	7
B Immunosuppressed (IS) rats	8	9
C Transfused 4/52	9	9
D Transfused 2/52	9	9
E Transfused 4/52 plus IS	9	9
F Transfused 2/52 plus IS	9	22

Using the Wilcoxon rank sum test, rats of group A had significantly shorter graft survival times than any other group ($P<0\ 01$). Groups B, C, D and E did not differ from one another, but group F showed significant prolongation of graft survival over all other groups ($P<0{\cdot}01$).

Following transfusion alone (DA to WAG) there was a highly significant fall in the two-way mixed lymphocyte reaction (PVG/C × WAG), most evident between 2 and 3 weeks after transfusion, subsequently returning towards pretransfusion levels. There was a simultaneous rise in the ability of plasma following transfusions to inhibit the responses of sensitized lymphocytes to antigen.

Thus, transfusions given 2 weeks before transplantation were more beneficial to graft survival than those given 4 weeks before transplantation. This correlated with a fall in the mixed lymphocyte reaction, and a rise in the lymphocyte inhibitory activity of plasma. These observations may have implications in human clinical transplantation.

62. What is the correct dose of *Corynebacterium parvum*?

H. D. MITCHISON and J. E. CASTRO, *Urology Unit, Department of Surgery, Royal Postgraduate Medical School, Hammersmith Hospital, London*

This study in mice was designed to compare the effects of a single high dose (466 μg), single low dose (70 μg) or multiple low doses of intravenous *Corynebacterium parvum*. Multiple injections were given weekly for 6 weeks.

All treatments decreased body and thymus weights, increased spleen weight threefold and liver weight twofold. Changes were maximal at 2 weeks, reverting to normal within 5 weeks. Repeated treatments raised a higher titre of anti-*C. parvum* agglutinating antibodies than a single dose (26 $\log_2$ compared with 8 $\log_2$).

Single low dose *C parvum* given at the time of implantation of Lewis carcinoma, day 0, significantly decreased primary tumour growth and inhibited pulmonary metastases. Multiple treatments had no additional effect. Survival was significantly prolonged by a single low dose on day 7, but not when given on day 13. Repeated treatments gave no extra protection.

Pretreatment with multiple doses counteracted the anti-metastatic effect of *C. parvum* when given at the time of tumour implantation. Abrogation still occurred after treatment-free intervals of 50 days and 90 days.

We conclude from these studies that a single dose of 70 μg is effective against the Lewis lung tumour. Multiple doses are no more effective, and when given before tumour may inhibit the beneficial effects of *C. parvum*. The underlying mechanisms are under investigation.

63. Urinary β-thromboglobulin in venous thromboembolism

R. C. SMITH, JOAN DAWES and C. V. RUCKLEY, *Royal Infirmary and MRC Radioimmunoassay Team, Edinburgh*

β-Thromboglobulin is released from platelets during aggregation and may be a marker for venous thromboembolism. Plasma estimation of β-TG has been shown to be of limited clinical value (Smith et al., 1978). Is urine sampling of more value?

Plasma and urine samples were obtained from 7 patients with proved venous thrombosis and from 11 patients without evidence of thrombotic disease.

	DVT ($n = 7$)	No DVT ($n = 11$)	
Urine			
No. of samples	24	12	
Mean (μg/l)	1·4	0 19	$t = 6{\cdot}06$
Range (μg/l)	0·12–2 0	0 15–0·2	$P<0{\cdot}001$
Plasma			
No. of samples	10	12	
Mean (μg/l)	539	305	$t = 0{\cdot}6$
Range (μg/l)	16–4000	24–1725	$P>0{\cdot}5$

All patients with DVT showed elevated urinary levels of β-TG and only one patient had normal levels at any stage during the 2-day study period. All patients without DVT showed normal levels. The difference between the means was highly significant.

There was no difference in the plasma levels between the two groups. However, elevated urinary levels were also detected in patients without evidence of venous thrombosis up to 14 days after surgery—in one patient with a ruptured Baker's cyst and in one with cellulitis.

Urinary β-thromboglobulin assay appears to be a more valuable discriminant in venous thromboembolism than the plasma assay.

SMITH R. C., DUNCANSON J., RUCKLEY C. V. et al. (1978) Thromboglobulin and deep vein thrombosis. *Thromb. Haemostasis.* 39, 338–345.

64. The significance of the popliteal valve in relation to ambulatory venous pressure and ulceration

J. FERNANDES E FERNANDES, K. SHULL, J. HORNER, J. T. HOBBS, T. N. NEEDHAM and A. N. NICOLAIDES, *Academic Surgical Unit and Vascular Laboratory, St Mary's Hospital Medical School, London*

Forty-two limbs (38 patients) who had had deep venous thrombosis (DVT) extending into the femoral or iliofemoral segment at least 5 years earlier and 10 limbs of 10 healthy volunteers were studied. The ambulatory venous pressure was measured by inserting a needle in a vein on the foot; the presence of reflux in the popliteal vein was determined by a directional Doppler ultrasonic blood velocity detector. All patients had ascending venography.

No. of limbs	IF or F segment	Popliteal valve	No. of limbs with ulceration	Mean AVP±s.d. (mmHg)
10	Normal	Competent	0	20±11
3	IF recan.	Competent	0	22±10
9	IF recan.	Incompetent	3	65±17
5	IF occ.	Competent	0	43±15
14	IF occ.	Incompetent	10	82±16
1	F recan.	Competent	0	24
3	F recan.	Incompetent	3	51±8
1	F occ.	Incompetent	1	70

F, Femoral; IF, iliofemoral; AVP, ambulatory venous pressure; recan., recanalization; occ., occlusion.

The results suggest that the most important factor in determining the ambulatory venous pressure and ulceration in post-phlebitic limbs is the condition of the popliteal valve. Ulceration does not occur even in the presence of occlusion if the popliteal valve is competent. The extent of DVT and recanalization or the failure of recanalization are of secondary importance.

65. Objective evaluation of speech after major oral surgery

P. J. BRADLEY, L. HOOVER and P. M. STELL, *Department of Otolaryngology, University of Liverpool*

Speech was quantified using a word list of monosyllables of all the 19 English consonants, 24 consonant clusters and 21 vowels. The subjects read out each word from a card and a three-man jury wrote down what they heard. A score of one was given for a correct answer by each jury member. The discriminatory value of the resulting scores was calculated by the phi-index (Anderson, 1976), and on the basis of this a list was compiled of 50 words that were good discriminators, so that the maximum possible score was 150.

Forty-six patients who had undergone major oral surgery and 47 normal subjects were studied. The normal subjects' scores ranged from 100 to 146 (median 138). Since a minimum of 40 per cent of phonemes is required for intelligible speech, the scores can be divided as follows: 0–60 as unintelligible, 60–100 as intelligible but impaired and over 100 within the normal range. The results for the patients (Table) show that the two factors which render a patient unintelligible are ankylosis of the tip of the tongue and a soft palate defect. Pure loss of bulk is much less important. This result questions the value of replacement by a distant skin flap merely to replace bulk.

	Score		
	100–150	60–99	0–59
Loss of bulk	12	4	0
Ankylosis of tip of tongue	0	0	5
Soft palate defect	0	0	4

ANDERSON J. (1976) *The Multiple Choice Question in Medicine.* London, Pitman Medical.

66. Acute painless abdominal distension and lung infection

R. M. HEDDLE and SHELAGH L. CALVERT, *Surgical Unit, Westminster Medical School, London*

It has been suggested that hypoxaemia following abdominal surgery is due to distension, pain and analgesics (Wahba et al., 1975). Good correlation exists between functional residual capacity (FRC), closing volume (CV) and arterial oxygenation (Nunn et al., 1978).

The purpose of this study was to investigate the effect of acute painless abdominal distension on CV and FRC. Five healthy volunteers underwent acute abdominal distension by instilling 3 l of Hartmann's solution into the stomach via a nasogastric tube over 1 h. FRC and CV were measured pre- and post-distension, using a helium dilution technique (Green and Travis, 1972). The results are shown in the Table.

	Subject				
	1	2	3	4	5
FRC (litres)					
Control	3·01	3·99	2·73	3·58	3·76
Post-distension	2·29	1·90	1·24	2·51	2·38
			$t = 5{\cdot}9$ $P < 0{\cdot}002$		
CV (litres)					
Control	0·500	0·660	0·490	0·600	0·650
Post-distension	0·775	1·100	0·600	0·850	1·100
			$t = 4{\cdot}8$ $P < 0{\cdot}005$		

This study has shown that acute painless abdominal distension causes significant respiratory dysfunction.

67. The role of nodal disease in primary lymphoedema

J. H. N. WOLFE, D. L. RUTT and J. B. KINMONTH, *Surgical Unit, St Thomas's Hospital, London*

Primary lymphoedema is generally thought to be a disease of peripheral lymphatics and less consideration has been given to the role of lymph nodes in this process. Distal hypoplasia is associated with a good prognosis, but proximal obstructive hypoplasia is associated with a progressively severe form of lymphoedema.

The morphology of inguinal lymph nodes has been studied in 42 patients with primary lymphoedema and compared with inguinal nodes. One patient had Milroy's disease, two had megalymphatics and the rest had primary hypoplasia. In this last group 19 had distal hypoplasia, 11 had obstructive hypoplasia and 9 had a mixed lymphographic picture.

The histological findings are correlated with the lymphographic and clinical appearances in the different groups. There was a dense cortical fibrosis in the nodes of 12 patients (32 per cent) which was associated with obliteration of the adjoining afferent lymphatics. The process was unrelated to episodes of cellulitis or duration of disease. The severity of the nodal and clinical changes were related and 10 of the 12 patients with cortical fibrosis had swelling of the whole limb.

The results suggest that in patients with proximal obstruction on lymphography, the primary disease may be in the nodes and not in the peripheral vessels.

68. Do patients eat enough after colon surgery?

C. K. YEUNG, A. F. HACKETT and G. L. HILL, *University Department of Surgery, The General Infirmary, Leeds*

Some patients after major surgery suffer from protein energy malnutrition. It is not known if the magnitude of the energy deficit is related to deficient food intake in the postoperative period.

We have studied voluntary food intake and energy balance in 6 male and 6 female patients over a 2-week period following elective colon surgery. Daily voluntary food intake was recorded by weighing all food consumed by the patient and home voluntary food intake was estimated by a dietary history technique. Energy balance was calculated from the voluntary food intake and from the changes in body fat and protein over the study period (Hill et al., 1978).

Eleven patients who had an uncomplicated recovery began to eat 2–7 days after the operation, reaching a maximum voluntary food intake between 7 and 14 days. The maximum voluntary food intake reached during this period was closely related to the home voluntary food intake ($r=0{\cdot}84$; $P<0{\cdot}01$).

There was no correlation between postoperative voluntary food intake and energy output over the study period. The higher the energy output, the more energy was derived from endogenous fat and protein. An average energy deficit of 1155 kcal per day (range +197 to −2758) was observed, and there was no significant relationship between this deficit and the voluntary food intake, which averaged 949 kcal per day (range +371 to +1833).

It is concluded that the amount of food consumed by patients postoperatively is determined by their previous home intake and not by their energy output. Patients with high energy outputs do not compensate by increasing voluntary food intake and large energy deficits can develop.

Correspondence

Abdominal tuberculosis

Sir,

Please permit me to make a few belated comments on the article entitled 'Abdominal tuberculosis in the 1970s; a continuing problem' by Shukla and Hughes (*Br. J. Surg.* **65**, 403–405). In this paper the authors have drawn attention to the difficulties in making a diagnosis of abdominal tuberculosis using the standard methods.

Two diagnostic aids that may be helpful in this condition are (*a*) peritoneoscopy and (*b*) the humbler diagnostic abdominal tap. Udwadia (1978), in a series of 384 peritoneoscopies, found tubercular lesions in 29 cases. These 29 cases were patients with abdominal symptoms and signs in whom all the standard tests had proved unhelpful. Udwadia concludes in his paper that peritoneoscopy has a 'great deal to offer' in the diagnosis of abdominal tuberculosis when it presents as ascites of obscure origin, with recurrent and chronic abdominal pain, with a lump in the abdomen and with pyrexia and loss of weight.

In 2 patients with abdominal symptoms seen at this hospital we were able to demonstrate AFB in the fluid obtained on diagnostic abdominal tap. One patient, while under treatment for pulmonary tuberculosis, developed abdominal distension and ascites some 18 months later. AFB were demonstrated on the third tap, thus firmly confirming our tentative diagnosis of abdominal tuberculosis. Incidentally, the value of repeated examinations of a pathological fluid is demonstrated. The second patient had no frank ascites.

Regarding the difficulty in diagnosing abdominal tuberculosis even at laparotomy referred to by Shukla and Hughes, we feel that if the omentum is adherent to the lesion, this favours an inflammatory rather than a neoplastic lesion. In this connection one has to state that the behaviour of the omentum in various intra-abdominal conditions does not seem to have been studied in depth.

Book reviews

Surgery of the Pancreas: a Text and Atlas

Edited A. M. Cooperman. 280 × 215 mm. Pp. 257+xiv, with 273 illustrations. 1978. London: Kimpton. £35·70.

THIS is an interesting volume, the authors having set out to produce a text and atlas of pancreatic disease for the practising clinical surgeon and surgical resident. The text is commendably brief and the illustrations clear and concise. I especially liked the brief concluding sections of personal observations and preferences which accompany some chapters. Somewhat less satisfactory is the approach to diagnosis which, while outlining in a capable manner the modern diagnostic techniques available, fails to arrange them in an order of priority and give them an overall evaluation. There is little cross-reference between the various diagnostic techniques mentioned and missing from this section of the book is the argued personal approach so evident in the section on operative management. The relationship of particular diagnostic techniques to surgical approaches and to operability is not well covered and the advantages and disadvantages of intraoperative diagnostic techniques are not sufficiently underlined.

There is a full discussion of contentious issues, such as the value of intraoperative biopsy of the pancreas and the operative treatment of acute pancreatitis. The section on pseudocyst is well presented but perhaps reveals an under-appreciation of the value of information to be gained from preoperative ultrasonic examination. The coverage of chronic pancreatitis is adequate for the average surgeon but perhaps somewhat brief for the specialist in the field, the real difficulties such as the necessity for total pancreatectomy and the niceties of the operation of subtotal pancreatectomy being dealt with somewhat sketchily. By contrast, there is a large section on thoracic splanchnicectomy and sympathectomy for relief of pancreatic pain despite the apt comment that the procedure seldom gives long term relief.

The discussion on cancer of the pancreas and periampullary region is comprehensive. Adequate mention is made of the use of diagnostic tests and the advisability of two-stage operation in some situations where the bilirubin level is high and renal function compromised. There is perhaps less comment than one would like to see on the recent, more frequent use of total pancreatic resection for pancreatic cancer and recent advances in this area require fuller discussion. The operation of pancreaticoduodenectomy is described at length and well illustrated, but again there is little discussion of the dangers and postoperative complications which may result, and a somewhat tedious homage to the views of George Crile jun. in his advocacy of conservative measures.

This book can be recommended for the general surgeon who is faced with an operative problem in pancreatic surgery and is of interest to the specialists.

L. H. BLUMGART

Pathology of Peripheral Nerves

Arthur K. Asbury and Peter C. Johnson. 270 × 185 mm. Pp. 311+xii. Illustrated. 1978. Eastbourne: Holt–Saunders. £15·00.

THE main aim of this excellently produced and very readable book is to educate general pathologists in a field that is often a mystery to them, and because of this orientation it will be a valuable reference book for all who have occasional contact with peripheral nerves. The presentation of modern ideas about peripheral nerves and their disorders simply, concisely and fully makes this book a must for specialists also. Trauma, tumours, metabolic and diabetic neuropathies are general topics covered and there is a useful practical description of the technique of sural nerve biopsy. The quality of the photomicrographs is outstanding.

PAMELA M. LE QUESNE

A Practice of Anaesthesia

Edited H. C. Churchill-Davidson. 4th edition. 240 × 160 mm. Pp. 1542+xviii. Illustrated. 1978. London. Lloyd-Luke. £26·00.

THE fourth edition of this standard anaesthetic text will maintain its position on the reading list of every postgraduate student of the subject. This edition has lost one of its founder author/editors, Dr Wylie, but has increased the number of assistant editors who cover a wide range of special interests.

There are many changes. The assistant editors have completely rewritten some chapters and expanded others, though the book retains its form and clarity of layout. Many of the original illustrations and diagrams are included, which will give the book a 'familiar' appearance for those who have used it extensively for reference and examination preparation.

Chapters on paediatric anaesthesia, placental transfer and the development of anaesthetic apparatus are included in this volume for the first time. The chapter on paediatric anaesthesia enables the non-specialist postgraduate student to find the basic information assembled in logical order. Dr Reynolds's excellent chapter on placental transfer of respiratory gases and drugs provides a welcome addition to the text. The outline of the development of anaesthetic apparatus is most interesting to read, with illustrations of these historic pieces of equipment which many readers may never have had the opportunity to see.

Other changes include reference to the role of prostaglandins, a description of the more recent anaesthetic agents, the now commonly used circulatory support drugs and a less detailed but broader description of mechanical ventilation and ventilators. In keeping with current development, SI units are included, but unfortunately only in parentheses.

J. HULF

Guide to House Surgeons in the Surgical Unit

G. J. Fraenkel, J. Ludbrook and H. A. F. Dudley. Sixth edition. 150 × 120 mm. Pp. 203+xii. Illustrated. 1978. London. Heinemann. £2·90.

THIS is an excellent book filling a gap between university graduation and the fully qualified, registered state through which young doctors have to survive many pitfalls. The main theme of the book is to give the houseman a thorough understanding of his role in a modern teaching hospital, without at any time forgetting that the whole aim of the exercise is to provide diagnosis and treatment combined with consideration and kindness for the sick patient. Most housemen will know in theory what should be done, but in practice and in order of preference many investigations require programming. This exercise runs from the personal touch, following up request cards by telephone calls, fulfilling the role of guide, philosopher and friend to patients, and at times that of minor executive in regard to senior colleagues while at the same time listening to advice from all paramedical and non-medical personnel who, as this book says, 'by their very permanence have a knowledge and authority which can be most useful if properly exploited!' The influence of one of its authors can be seen particularly in the flow diagrams for dealing with patients who have, for example, retention of urine, undiagnosed liver disease and postoperative mental dysfunction; this latter flow chart, however, seems to have been photoreduced to fit the page and certainly reminded this reviewer that it is several years since he had the visual acuity of a houseman! Some change of typeset would encourage and help clarity in this figure. That apart, the book is to be warmly and wholeheartedly recommended to those embarking on a career as a houseman, for it is up-to-date, well indexed and full of good counsel from experienced authors. It also fits neatly into a white coat pocket.

J. B. ELDER

Frobisher and Fuerst's Microbiology in Health and Disease

Robert Fuerst. Fourteenth edition. 250 × 166 mm. Pp. 648+ix. Illustrated. 1978. Eastbourne: Holt–Saunders. £10·00.

Review of Medical Microbiology

E. Jawetz, J. L. Melnick and E. A. Adelberg. Thirteenth edition. 260 × 185 mm. Pp. 550+xiv. Illustrated. 1978. Los Altos, Ca. Lange. $12.00.

BOTH of these 1978 editions give a wide coverage of microbiology but one gains the impression that, of the two books, the microbiology review is the more up to date. Both apportion considerable space to bacterial physiology and genetics and rudimentary immunology, which, though of interest, are not directly relevant to surgical practice. However, despite the inevitable overlap of subject content they are in many ways complementary to one another rather than repetitive.

Frobisher and Fuerst's contribution is perhaps best described as being toward the 'ecology of microbiology'. Diseases and organisms are discussed from the standpoint of their environmental origin so that anthrax and gas gangrene, for example, are grouped together under 'bacterial pathogens of the soil'. Commensurate with this environmental approach, 'factors in transmission of communicable disease' and the role of 'microorganisms in our ecological system' are discussed. An entire section is also included in which the topics of sterilization, disinfection and a general consideration of antibiotics and chemotherapy are presented.

By contrast the *Review of Medical Microbiology* devotes more than half of its 41 chapters, concisely but without excessive detail, to a systematic description of bacteria, fungi, viruses and parasites which includes their pathogenesis, diagnosis and treatment. This method of approach lends itself more readily to the surgeon seeking information regarding a microbiological problem. There is also discussion of practical relevance regarding the use of the more commonly employed 'hospital' antibiotics and a chapter on the 'principles of diagnostic medical microbiology', which may well have been written more for the surgeon (or physician) than the microbiologist.

In conclusion, despite the readability and excellent illustrations of Frobisher and Fuerst's textbook, one feels that it would be to the *Review of Medical Microbiology* that the surgeon would turn in time of need.

MICHAEL J. SHIELD

Surgical Skills in Patient Care

Charles W. Van Way III and Charles A. Buerk. 265 × 185 mm. Pp. 173. Illustrated. 1978. St Louis: Mosby. £9·20.

THERE has been a tendency in recent years to disparage technical skill in medicine in favour of controlled trials and *P* values. On the other hand, mere technique must not be an end in itself. That is why the title of this book is so apt—it puts surgical skills in their right context. The procedures described are those used by all kinds of doctors in everyday patient care. The authors have been involved in teaching techniques such as asepsis, suturing, tying knots, local nerve blocks and wound care to junior doctors and students and the book is the result of that experience.

It is very readable, more so than some larger, older books on the subject. The diagrams are clear and appropriate and the ring binding means that the pages lie open while a particular procedure is being studied. This is particularly useful when following the instructions on tying knots! The sections are concise enough for the doctor to revise the technique before doing a liver biopsy, cut-down or tracheostomy.

One or two errors detract a little from the overall authority of the book: for example, if a chest drain is secured by a suture criss-crossing obliquely up the drain (p. 120), when the loops slip down and become transverse they will loosen and the drain will come out; the diagram of the subcuticular wound closure (p. 64) makes the suture look distinctly subcutaneous.

An extensive index adds to the overall usefulness and the book as a whole can be warmly recommended.

A. G. JOHNSON

Basic and Clinical Immunology

Edited H. H. Fudenberg, D. P. Stites, J. L. Caldwell and J. V. Wells. Second edition. 255 × 180 mm. Pp. 758. Illustrated. 1978. California. Lange. $14.50.

THIS very large book covers all aspects of immunology. Your reviewer has studied those chapters of surgical interest. As this is a multi-author book (with a dazzling cast), the comments may not reflect the whole picture.

The book is well laid out with clear diagrams. References appear at the end of each chapter; however, they are not cited in the text and they could be more comprehensive.

The chapter on transplantation immunology is brief and well written, with a good concluding overview; it has unfortunately been overhauled by recent developments in DR antigen matching. The same author contributes a longer chapter on the histocompatibility complex, but at the expense of this, the surgeon would surely prefer a fuller account of transplantation immunology; nowhere is there a detailed account of the events in acute rejection. Similarly a chapter on immune cell traffic might have been included. The chapter on tumour immunology is a model of good writing and is to be recommended to anyone with even a passing interest in the subject. Cellular and non-cellular mediators of the immune response are well described as are the tests of cellular function.

Overall, a well-written book, with the emphasis on clarity. The book is not comprehensive enough for a reference book yet it is too large for the primary fellowship; however, at the price it is an exccellent buy for anyone beginning to take a serious interest in immunology.

R. W. BLAMEY

Nervous Tunnel Syndromes of the Limbs from Non-traumatic Etiology

N. Marchetti, P. Bachechi, E. Barbieri and G. Guido. 245 × 180 mm. Pp. 188. Illustrated. 1978. Padova: Liviana Editrice. No price given.

MOST orthopaedic surgeons have dealt with several varieties of 'tunnel syndromes' and have read of many more. Those specializing in the surgery of peripheral nerves will have had a wider experience, but few can have seen the encyclopaedic collection described by the authors of this book. All the recognized non-traumatic varieties of peripheral nerve compression are described. The text is in Italian and there is a parallel English version: the text is well illustrated.

The style is dogmatic and the English translation quaint. I was particularly interested in the section on writer's cramp, said by the authors to be due to compression of the median nerve in the forearm, but different from the pronator teres syndrome. Physical and electromyographic signs were absent but decompression of the nerve relieved the symptoms.

This book should find a place on the shelves of libraries and of those surgeons interested in the surgery of peripheral nerves; it will be a useful reference book. I would not recommend it for undergraduates or for trainee surgeons, since it may give them the false impression that there is nothing more to be added to the subject.

M. WATSON

Gynaecological Laparoscopy

The report of the working party of the confidential inquiry into gynaecological laparoscopy. 210 × 150 mm. Pp. 165. Illustrated. 1978. London: Royal College of Obstetricians and Gynaecologists.

THIS important volume has been well reviewed in a number of places and deservedly so. It represents a formidable amount of work but more important, as with the confidential obstetric inquiries, an honest analytical approach which surgeons in other fields could do well to emulate. Some form of audit (a word used fearlessly in the introduction) is coming upon us. The techniques and attitudes described here are a model for self-protective audit, which we should adopt, lest it is done for us, and possibly against us, by others.

H A. F. DUDLEY

SURGICAL PROBLEMS IN THE AGED

Edited by K. D. J. VOWLES, MB, CHB, FRCS
Consultant Surgeon, Devon and Exeter Clinical Area

with a Foreword by
SIR FERGUSON ANDERSON, OBE, MD, FRCP, FRFPS, KStJ

Contents: Foreword; Surgery for the aged; Assessment before surgery; Anaesthesia for the aged; The problem of dysphagia; Gastroduodenal problems; Biliary tract and pancreatic problems; Problems with hernia, the small intestine and the appendix; Colonic and rectal problems; Urological problems; Problems of the aged hip; Vascular problems and the aged amputee; Postoperative problems in the aged; Index.

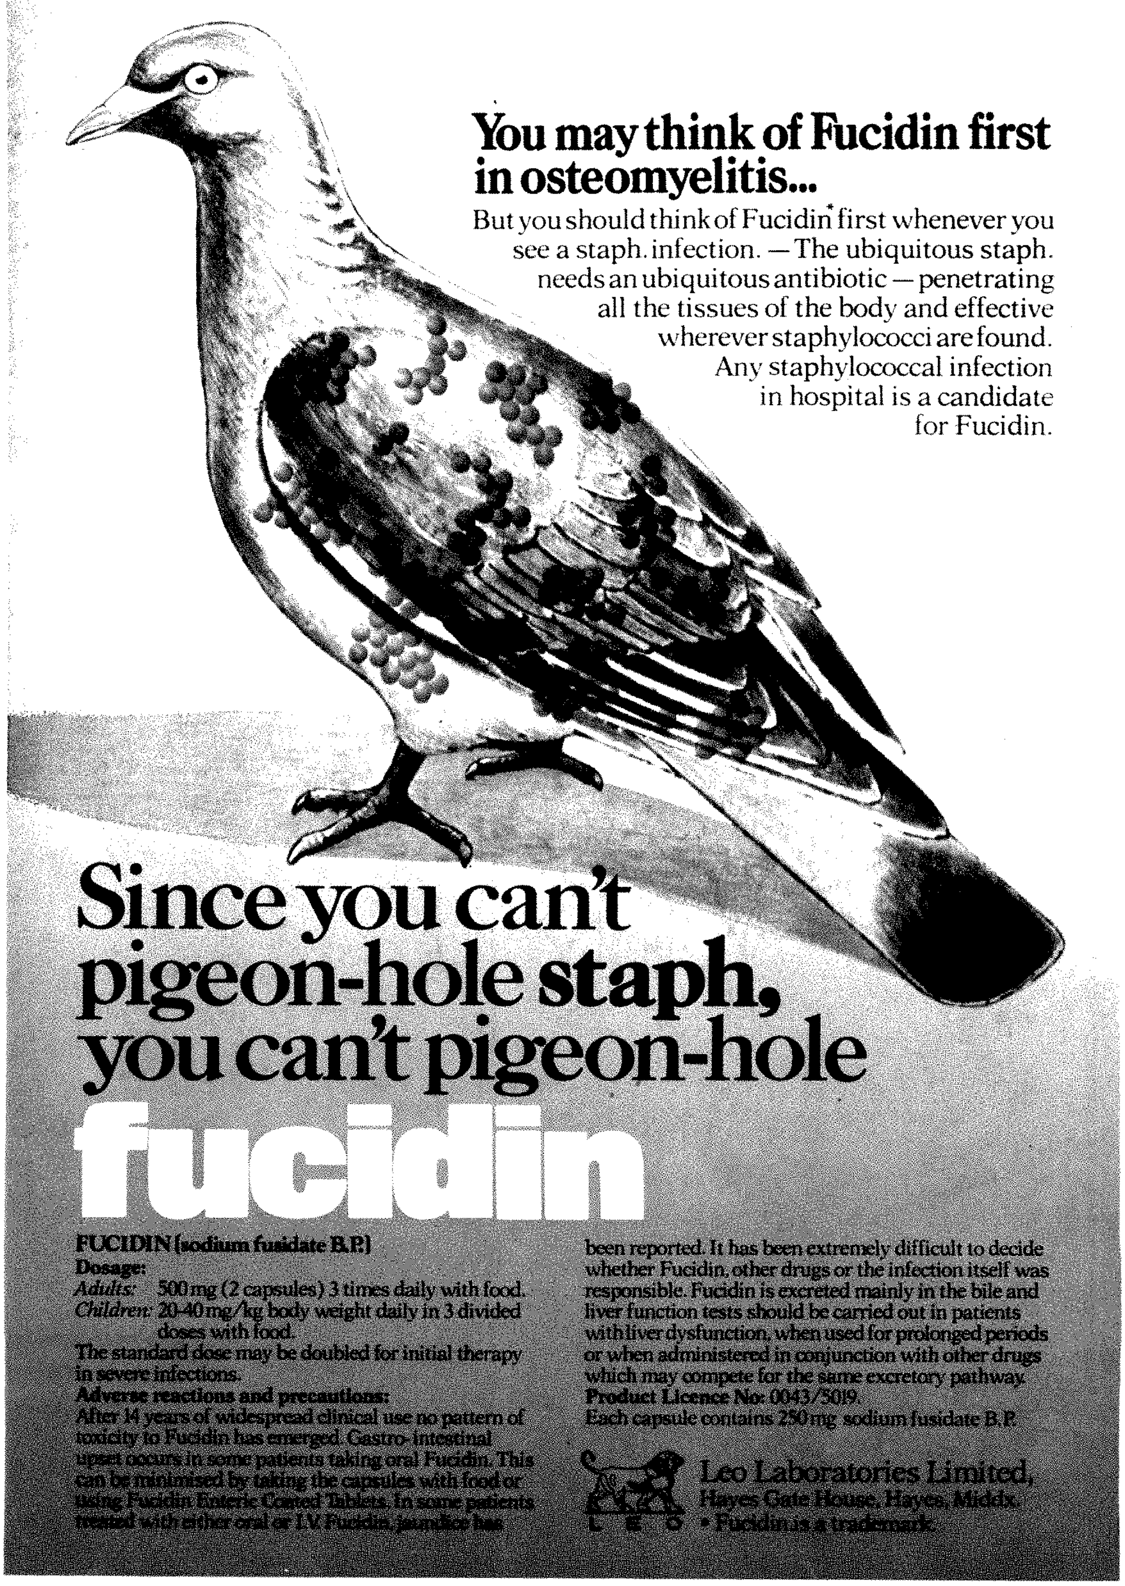
The rapidly rising proportion of aged patients in hospitals means that more are needing both acute and planned surgery. Many are living an active and independent life which is interrupted by a problem requiring surgery for its cure.

This study of the presenting problems of aged surgical patients in a district general hospital shows how many of them can be restored to active and enjoyable life, emphasizing, often in line with a patient's own wishes, that its quality should be at least as much the surgeon's concern as its length.

The book is an actual record of results covering a wide range of practical problems and each chapter is written by an expert in his own field.

216 × 138mm, 208 pages, 20 illustrations **UK net price £8·50**

JOHN WRIGHT
42–44 Triangle West, Bristol BS8 1EX



You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. —The ubiquitous staph. needs an ubiquitous antibiotic — penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole fucidin

FUCIDIN [sodium fusidate B.P.]
Dosage:
Adults: 500 mg (2 capsules) 3 times daily with food.
Children: 20-40 mg/kg body weight daily in 3 divided doses with food.

The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:
After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.

Product Licence No: 0043/5019.
Each capsule contains 250 mg sodium fusidate B.P.

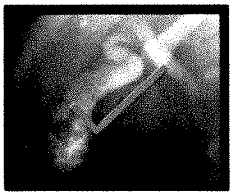
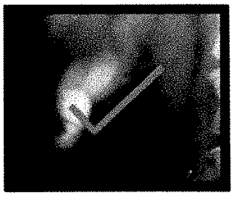
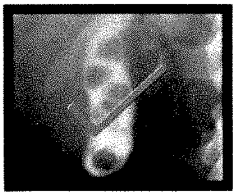
STOL

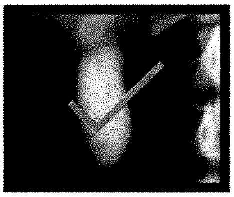
Chendol

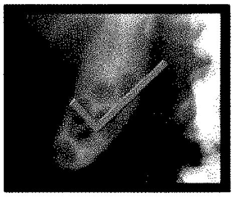
What proportion of stones are suitable?

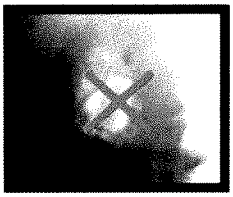


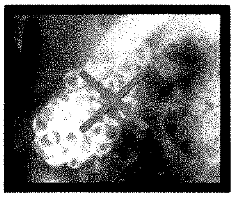


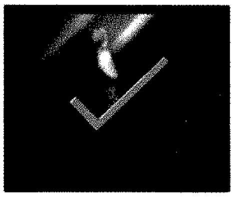












80%

Chendol can remove gallstones without surgery

Chendol solubilises 80% of all gallstones

CHENDOL acts on all mixed stones and cholesterol stones that are not calcium coated by reducing the amount of cholesterol secreted into the bile. Precipitated cholesterol is solubilised.

INDICATIONS For dissolution of gallstones. Cholesterol stones coated with calcium or stones composed of bile pigments are not dissolved by chenodeoxycholic acid.

DOSAGE The present clinical evidence suggests that optimum results will be obtained on a dose level of 10 - 15 mg per kg. body weight daily in divided doses.

CONTRAINDICATIONS, WARNINGS, ETC. CHENDOL should not be administered to patients with radio-opaque calcified gallstones nor to patients with non-functioning gallbladders, nor to patients with chronic liver disease, nor with inflammatory diseases of the small intestine and colon.

CHENDOL should not be administered to women who may become pregnant.

CHENDOL is generally well tolerated; the only side effects reported to date are diarrhoea and pruritus. It has been found that after a slight reduction in dose for a few days, diarrhoea ceases and the dose can then be gradually increased to the former level. Laboratory monitoring should accompany treatment.

Results of recent studies have demonstrated a 93% success rate in the U.K.[1] and 81% in the U.S.A.[2] for solubilising cholesterol rich radiolucent gallstones in suitable patients.

Each CHENDOL capsule contains 125 mg of chenodeoxycholic acid.
Available in securitainers of 100 capsules - N.H.S. cost £13.50 per pack
500 capsules N.H.S. cost £65.00 per pack

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, John Wright & Sons Ltd, Broadmead House, 21 Panton Street, London SW1Y 4DR*. Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the journal unless rights are reserved before publication.

Business communications should be sent to *John Wright & Sons Ltd, British Journal of Surgery, Bristol BS8 1EX*. Remittances are payable to the *British Journal of Surgery*.
Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

Manuscripts

The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations

It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978: **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors*. London, Pitman, 1978.

References

In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus*. Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).

You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. — The ubiquitous staph. needs an ubiquitous antibiotic — penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole

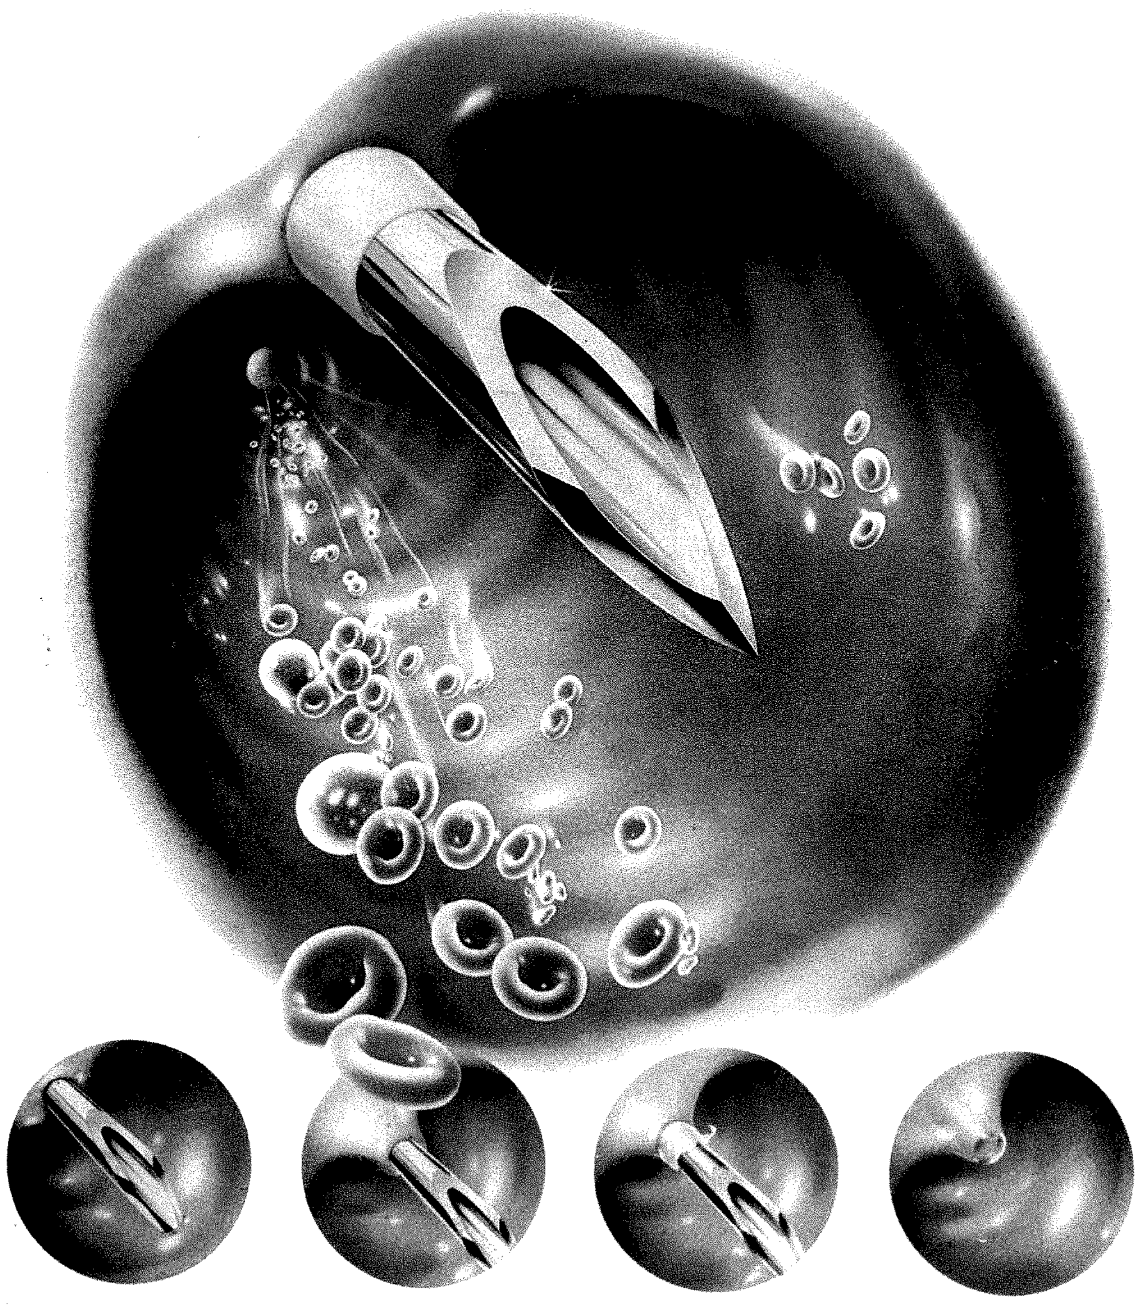
The intravenous difference



Where the distance between the cannula tip and the heel of the needle bevel is too great, there is a risk of piercing the opposite vein wall before the cannula is satisfactorily placed within the lumen. With Abbocath®-T, the cannula tip fits snugly behind the heel of the short bevelled needle tip.

An abrupt cannula shoulder requires a high penetration force, leading to tissue and vein trauma, discomfort and repeat procedures. The electronically formed double-taper tip of Abbocath-T requires a minimal penetration force which is constant from cannula to cannula.

A thin cannula shoulder is likely to curl back or shear during insertion, irritating the vein intima and increasing the risk of thrombus formation and phlebitis. The Abbocath-T cannula tip is smooth and sturdy, with no ragged edges or thin spots, and never protrudes over the heel of the needle.

The cannula is left outside the vein lumen following needle withdrawal—resulting in unsightly haematoma and infiltration of i.v. fluid into the tissues. Abbocath-T helps obviate these risks by correct cannula positioning, rapid flashback, and smooth judder-free needle withdrawal.

Abbocath®-T

Not all the benefits are visible

A unique combination of clinically important properties.

The exceptional smoothness of a PROLENE Suture allows it to slide easily through the most delicate tissue. This permits suture line tension to be adjusted after placement, which is of particular benefit in Cardiovascular and Ophthalmic surgery.

It also aids easier removal of skin or sub-cuticular sutures even after prolonged implantation. In General surgery PROLENE Polypropylene starts strong and stays strong, providing long term wound support, whilst handling and knotting is easier than with other monofilament non-absorbables.

PROLENE* Monofilament Polypropylene

ETHICON

ETHICON Ltd., P.O. Box 408, Bankhead Avenue, Edinburgh EH11 4HE, Scotland.

Precautions PROLENE Polypropylene Sutures may not be resterilised more than three times by the standard autoclaving method without loss of strength. Care should be taken to avoid damaging the surface of the material with surgical instruments as this could lead to fracture of the material in use.

Danol

danazol

controls pituitary gonadotrophins without exerting oestrogenic or progestogenic activity

WINTHROP

For the treatment of endometriosis, infertility associated with endometriosis, fibrocystic mastitis, virginal breast hypertrophy, gynaecomastia, primary constitutional precocious puberty and other similar endocrine disorders where control of the release of pituitary gonadotrophins LH and FSH would be of therapeutic value.
Danol (danazol 200 mg). PL 0071/0095. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment £1.42 (3 capsules).
Danol-½ (danazol 100 mg). PL 0071/0094. Bottles of 100 capsules. Basic N.H.S. cost of one day's treatment 72 p. (3 capsules).
Dosage. Adults 200-800 mg daily, children 100-400 mg daily. See Data Sheet for details.
Contra-indications: Pregnancy.
Precautions. 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop.
Side Effects. Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control.
Danol is a trade mark. Further information available from:- Winthrop Laboratories Surbiton-upon-Thames Surrey KT6 4PH.

FRENCH'S INDEX OF DIFFERENTIAL DIAGNOSIS

11th Edition

Edited by F. DUDLEY HART, MD, FRCP
Physician, Westminster Hospital, London

With 16 contributors

French's Index of Differential Diagnosis covers the whole ground of medicine, surgery, gynaecology, cardiology, endocrinology, ophthalmology, neurology and dermatology. It is an invaluable reference on the application of differential diagnosis to all the main signs and symptoms of disease.

This book helps the practising physician to be sure that he has considered all the disorders that might be behind his patient's particular symptoms or physical signs. If, in a particular condition, a symptom attracts special notice, discussion of it may be found, often in more than one part of the book, by using the enormously comprehensive and exact index.

Profusely illustrated throughout with many new diagrams and photographs in both colour and black and white, this new edition of *French's Index of Differential Diagnosis* remains an outstanding reference book.

248 × 174 mm, 1016 pages.
808 illustrations of which 208 are in colour

The management of insulin tumours of the pancreas

L. P. LE QUESNE, J. D. N. NABARRO, A. KURTZ AND S. ZWEIG*

SUMMARY

A series of 26 patients diagnosed as having an insulin-secreting, islet-cell tumour of the pancreas is described. Three patients were treated medically, but in the remaining 23 the tumour was found at operation; 1 patient had a carcinoma with hepatic metastases, but in the other 22 the tumour was apparently benign and the subsequent course of these patients has confirmed this conclusion.

The tumour was found at the initial operation in 19 of the 22 patients with a benign tumour treated surgically. Of the other 3, the tumour was removed at a second operation in 2 and at a third operation in 1. Two of the 22 patients died following the operation.

Diazoxide was administered to 21 patients, before and/or after operation. It was given preoperatively to 17 patients, in all of whom it prevented the development of hypoglycaemic symptoms, but in 2 it caused serious fluid retention and had to be discontinued. Seven patients have been successfully treated with long term diazoxide, either as an alternative to surgery or following an unsuccessful operation, 1 of these being the patient with an islet-cell carcinoma. In these patients diazoxide has been given for up to 12 years without apparent side effects.

Selective coeliac angiography was performed in 13 patients. In no patient did it provide critical information that significantly influenced the treatment of the patient.

Percutaneous, transhepatic portal venous catheterization was performed in 4 patients and indicated the site of the tumour in 3, 2 of whom had had 1 previous operation and 1 had had 2 previous operations, at none of which was a tumour found: in all 3 patients the tumour was removed at a subsequent operation.

The application of these findings to the management of patients with an insulinoma is discussed and a scheme of management is proposed.

BETWEEN 1962 and 1978, 26 patients with an insulin-secreting tumour of the pancreas have been treated at The Middlesex Hospital. Our experience in the management of these patients is reported, with particular emphasis on the results of preoperative angiography in the localization of these tumours, and on the use of diazoxide in the control of hypoglycaemia. The management of patients with this condition is discussed in the light of this experience.

Patients and methods

The present series comprised 16 women and 10 men, their ages ranging from 18 to 70 years (*Table 1*). A benign tumour was removed from 22 patients: 1 patient (*Case* 2) had a carcinoma with metastases and the condition ultimately proved fatal. The 3 remaining patients were treated medically and their tumours are presumably benign.

All the patients presented with neurological symptoms, usually attacks of confusion, loss of consciousness or fits. Three patients, following typical, transient attacks occurring intermittently over several months, developed prolonged coma. Two of these (*Cases* 14 and 16) were admitted in a state of decerebrate rigidity; following maintenance of normoglycaemia with diazoxide a tumour was removed and both have made remarkable recoveries, although they have some permanent impairment of cerebral function.

Diagnosis

The diagnosis of hypoglycaemia was based on finding a low blood sugar ($<2\cdot2$ mmol/l) either after an overnight fast (18 patients) or during prolonged fasting (5 patients). In the other 3 patients the diagnosis was based on the history and on an abnormal blood sugar to serum insulin relationship. The fact that the hypoglycaemia was due to excess insulin was demonstrated by finding a disproportionately high serum insulin for the blood sugar either after overnight or prolonged fasting (*Fig.* 1).

In the first patient in the series the fact that the hypoglycaemia was of islet-cell origin was demonstrated by an intravenous tolbutamide test, but thereafter this test was not used as a diagnostic procedure.

Diazoxide

Diazoxide was given to 17 patients before operation. The initial dose was 50 mg 8-hourly. In all patients control of the blood sugar level and symptoms was successfully obtained, but to achieve this the dose had to be increased to 450 mg daily in several patients, and 1 patient (*Case* 14) required 1·2 g daily before control was achieved. In 2 patients the drug caused serious fluid retention, leading in one patient (*Case* 23, 150 mg daily) to left ventricular failure and in the other (*Case* 17, 450 mg daily) to a pericardial effusion. Both conditions resolved promptly on withdrawal of the drug.

In 3 patients (*Cases* 6, 18 and 22) no tumour was found at the initial operation and these patients were subsequently maintained symptom-free on diazoxide; details of these patients are given below. An operation has not been performed on 3 older patients (*Cases* 8, 12 and 25); their symptoms have been controlled on diazoxide, one of them having been on treatment with 150 mg/day for 7 years. Diazoxide was also

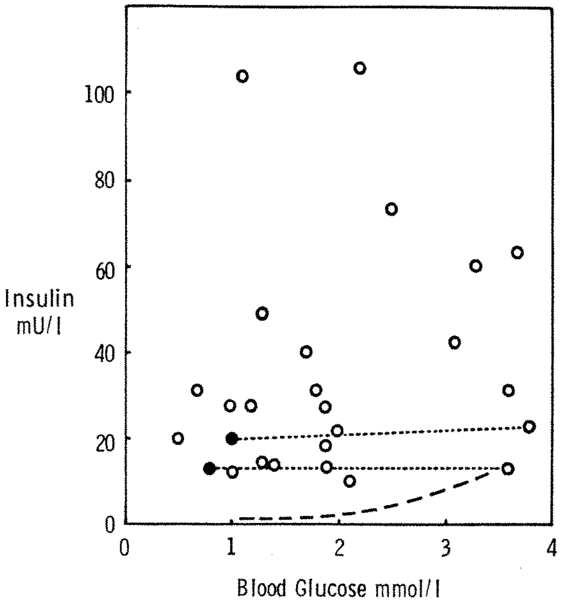

Fig. 1. Simultaneous fasting blood sugar and serum insulin levels in 24 patients with an insulinoma. The dashed line (– – –) represents the upper limit of serum insulin in 12 normal subjects rendered hypoglycaemic with fish insulin (Turner and Harris, 1974). The open circles (○) denote the levels obtained after an overnight fast. In 2 patients the overnight fast did not produce a diagnostic result and the test was repeated after a prolonged fast (●); in both patients this repeat test confirmed the diagnosis.

given to the patient with an islet-cell carcinoma with liver metastases; the attacks were controlled with this drug until the patient's death 10 months later.

Coeliac angiography

Coeliac angiography was performed preoperatively in 13 patients, subtraction films being made in 10. To assess the contribution of this examination to the management of each patient, the surgeon was not informed of the result of the angiogram before operation, and the films were consulted only when a tumour had been located or when the surgeon was satisfied that he could not find it.

In 10 of these 13 patients the tumour was found without undue difficulty. In 6 the tumour had been correctly located by the arteriogram. In 3 of the remaining 4 no tumour had been demonstrated on arteriography, and in the fourth patient the angiogram was reported as showing a tumour in the head of the pancreas whereas at operation a tumour was found in the tail; the patient was cured by resection of the tumour.

In 3 patients no tumour could be felt at operation. In 2 patients (*Cases* 6 and 18, *see below*) no tumour was demonstrated radiologically. In the third patient (*Case* 22, *see below*) the angiogram suggested, but did not definitely show, the presence of a tumour in the head of the pancreas, but even after repeated palpation it could not be indentified. The abdomen was closed without resection of any pancreatic tissue and at a subsequent operation a tumour was identified in the tail of the pancreas. The results of the angiographic examination are summarized in *Table II*.

The angiograms of 6 patients resulted in correct localization of the tumour. Five were in the head of the pancreas (maximum diameter 0·5–1·5 cm) and 1 in the body (diameter 2·0 cm). In 7 patients the tumour was not visible on the angiogram. Of these, 3 were in the tail (maximum diameter 0·8–1·5 cm), 2 in the body (0·8 and 1·5 cm diameter), 1 in the neck (0·8 cm diameter) and 1 in the uncinate process (1·2 cm diameter).

Operative treatment

In 23 patients the pancreas was explored through a transverse supraumbilical incision. In 19 a benign tumour was found at the initial operation, simple enucleation being performed in 13. In the remaining 6 patients, in whom the tumour was in the tail, a limited distal pancreatectomy, together with splenectomy, was performed. One of the patients having enucleation of the tumour from the head of the pancreas died postoperatively (*Case* 20); she developed a peripancreatic abscess requiring drainage, followed by prolonged ileus and a pancreatic fistula; death followed an episode of profuse vomiting with aspiration. The remaining 18 patients were cured by the removal of the tumour.

The management of the 3 patients in whom no tumour could be found at the original operation is described in detail, as is that of one patient (*Case* 23) who presented unusual diagnostic difficulties.

Case 6: Blind distal pancreatectomy was performed at the initial operation but no tumour was found in the resected specimen. The patient was adequately controlled on diazoxide for 2 years, when a further laparotomy was performed. No tumour was demonstrated on preoperative angiography and none was found at operation. Following this operation the patient remained symptom-free on diazoxide for 12 years, after which he again developed hypoglycaemic attacks, despite increasing doses of the drug. The results of a percutaneous transhepatic portal vein catheterization were difficult to interpret, but suggested the presence of a tumour at the junction of the head of the pancreas with the uncinate process. An ultrasound examination also indicated the presence of a tumour in the same area. At the third operation exposure of the pancreas was difficult owing to the presence of dense, very vascular adhesions. Eventually a soft tumour, almost impalpable in the surrounding gland, was detected in the uncinate process, posterior to the superior mesenteric vessels, and further severe haemorrhage occurred during its removal. Operation was followed by numerous complications and the patient eventually died, 63 days postoperatively, as the result of sepsis in the portal area. (The initial stages of this patient's history have been recorded previously by Mengoli and Le Quesne, 1967.)

Case 18: No tissue was excised at the first operation, and postoperatively the patient was treated with diazoxide. After 2 years he was requiring increasing doses of this drug but arteriography failed to reveal a tumour. Transhepatic catheterization of the splenic vein was performed by Dr R. Dick at the Royal Free Hospital, samples of blood being withdrawn at measured distances from the splenic hilum. The insulin content of these samples was measured and the results suggested the presence of an adenoma in the body of the pancreas. Following this a further laparotomy was performed but again no tumour could be palpated. A distal pancreatectomy was performed, the line of pancreatic division being judged from its relation to the lumbar spine to lie to the right of the indicated position of the tumour. Serial slicing of the removed portion of the pancreas revealed a 8-mm diameter adenoma 1 cm from the line of section. This patient has remained symptom-free since operation. (Details of the catheterization study in this patient have been reported by Turner et al., 1978.)

Case 22: Despite an arteriogram suggesting, but not definitely indicating, a tumour in the head of the pancreas, no tumour could be felt at operation. As a preoperative trial of diazoxide had shown that it would control the patient's symptoms, the abdomen was closed without resection of any pancreatic tissue. The patient remained symptom-free on diazoxide 150 mg daily, but was readmitted for reassessment 12 months later owing to a weight gain of 12 kg. Percutaneous transhepatic catheterization of the splenic vein (*Fig.* 2) indicated the presence of a tumour in the tail of the pancreas. At a second operation a 12-mm tumour was found in the tail of the pancreas, 4–5 cm from the tip. Distal pancreatectomy and splenectomy was performed and the patient made an uneventful recovery. The patient was mildly diabetic for 3 days after operation, excluding the presence of a second tumour in the head of the pancreas.

Case 23. This 31-year-old lady had had infrequent episodes of confusion for 5 years before referral to The Middlesex Hospital in 1977. On prolonged fasting the blood sugar fell to 1·3 mmol/l and the patient became confused. A number of overnight fasting blood sugar and insulin level measurements were made with the results shown in *Table III*. The first three pairs of blood sugar and serum insulin levels would lie above the dotted line in *Fig.* 1 while the last three fall below it. (The figures for January 1977 are shown in *Fig.* 1.) It seemed possible that this patient had an insulinoma that was only partially autonomous. Arteriography did not reveal a tumour. Diazoxide therapy led to pulmonary oedema and had to be discontinued. Two days after stopping the diazoxide transhepatic splenic vein catheterization was performed by Dr Dick, but the serum insulin levels were all low and there was no indication of the site of the adenoma. An untrasound scan suggested that there might be an adenoma in the neck of the pancreas.

At operation a dumb-bell-shaped tumour (maximum dimension 1·5 cm) was found in the distal part of the body of the pancreas; it was removed by distal pancreatectomy. Histological examination showed a benign islet-cell adenoma and the patient has remained free from attacks in the 18 months since operation.

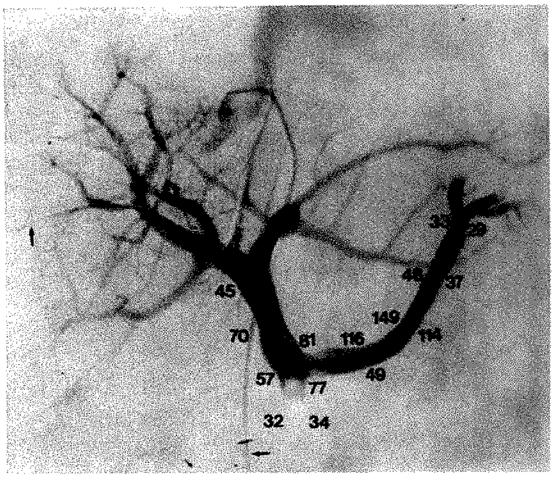

Fig. 2. Results of the percutaneous transhepatic catheterization study in *Case* 22. The concentration of insulin (mU/l) at measured intervals along the splenic superior mesenteric and portal veins is superimposed on a phlebogram. The catheter was passed twice along each of the former two veins, and the results of the two studies are shown on either side of each vein. The abrupt increase in concentration of insulin in the middle sample from the splenic vein clearly indicates the site of the tumour. In this patient, in addition to the catheter inserted into the portal system (↑), a catheter was also passed into a hepatic vein (←).

Discussion

The establishment of a firm diagnosis that a patient's symptoms are due to organic hyperinsulinism, the commonest cause in an adult being a solitary, benign adenoma of the B-cells of the islets of Langerhans, involves two steps: (*a*) the demonstration that the symptoms are caused by hypoglycaemia and (*b*) that this is accompanied by excess, inappropriate insulin secretion.

Once the possibility of the diagnosis has been considered it is usually a straightforward procedure to establish that the attacks are due to hypoglycaemia, a diagnosis firmly linked in surgical writings with the features of Whipple's triad. In the majority of patients the development of hypoglycaemia (blood sugar <2·2 mmol/l) can be provoked by an overnight fast, but as with 5 of our patients, a fast of up to 48 h may be required. With the development of sensitive methods of measuring serum insulin by immunoassay techniques it is now possible to provide direct evidence that the hypoglycaemia is due to hyperinsulinism, by demonstrating a disproportion between the fasting blood sugar and serum insulin levels (Turner et al., 1971, 1973; Turner and Harris, 1974). In a normal person, if the blood sugar falls to a low level, serum insulin becomes almost undetectable, but in a patient with an insulinoma, insulin secretion is no longer suppressed by this 'feedback' mechanism. It is usually possible to demonstrate this imbalance between sugar and insulin levels by measuring levels of both in an overnight fasting blood sample. Even if a clear imbalance is shown, it is wise to repeat the examination at least once, as its implications are so important. If hypoglycaemia is not provoked by this method, it may be necessary to prolong the fast for up to 48 h, as shown by two of the subjects in *Fig.* 1. If this is unsuccessful, hypoglycaemia can be produced by injection of a fish insulin that does not cross-react in the assay with human insulin, so that it is possible to detect whether endogenous insulin secretion has been suppressed by the hypoglycaemia (Turner and Harris, 1974). A further possibility is to produce hypoglycaemia by the injection of ordinary commercial insulin and monitor endogenous insulin production by measuring the level of C-peptide. This peptide is the connecting link between A and B chains of insulin and is released when any insulin is being secreted by the patient's pancreas.

Despite the wide recognition of the features of hypoglycaemia, the diagnosis of an insulinoma can be difficult. In a review of 60 patients with an insulinoma seen at the Mayo Clinic, Service et al. (1976) found that the time from the initial attack to the establishment of the diagnosis ranged from 10 days to 15 years, the average being 32·5 months. The importance of an early diagnosis is underlined by *Cases* 13 and 24 in the current series, both of whom suffered long periods of unconsciousness before the diagnosis was suspected and confirmed, and both of whom have some residual permanent impairment of cerebral function. It should be emphasized, however, that even if there has been severe cerebral damage, the tumour should be removed if possible, as a remarkable degree of recovery may occur.

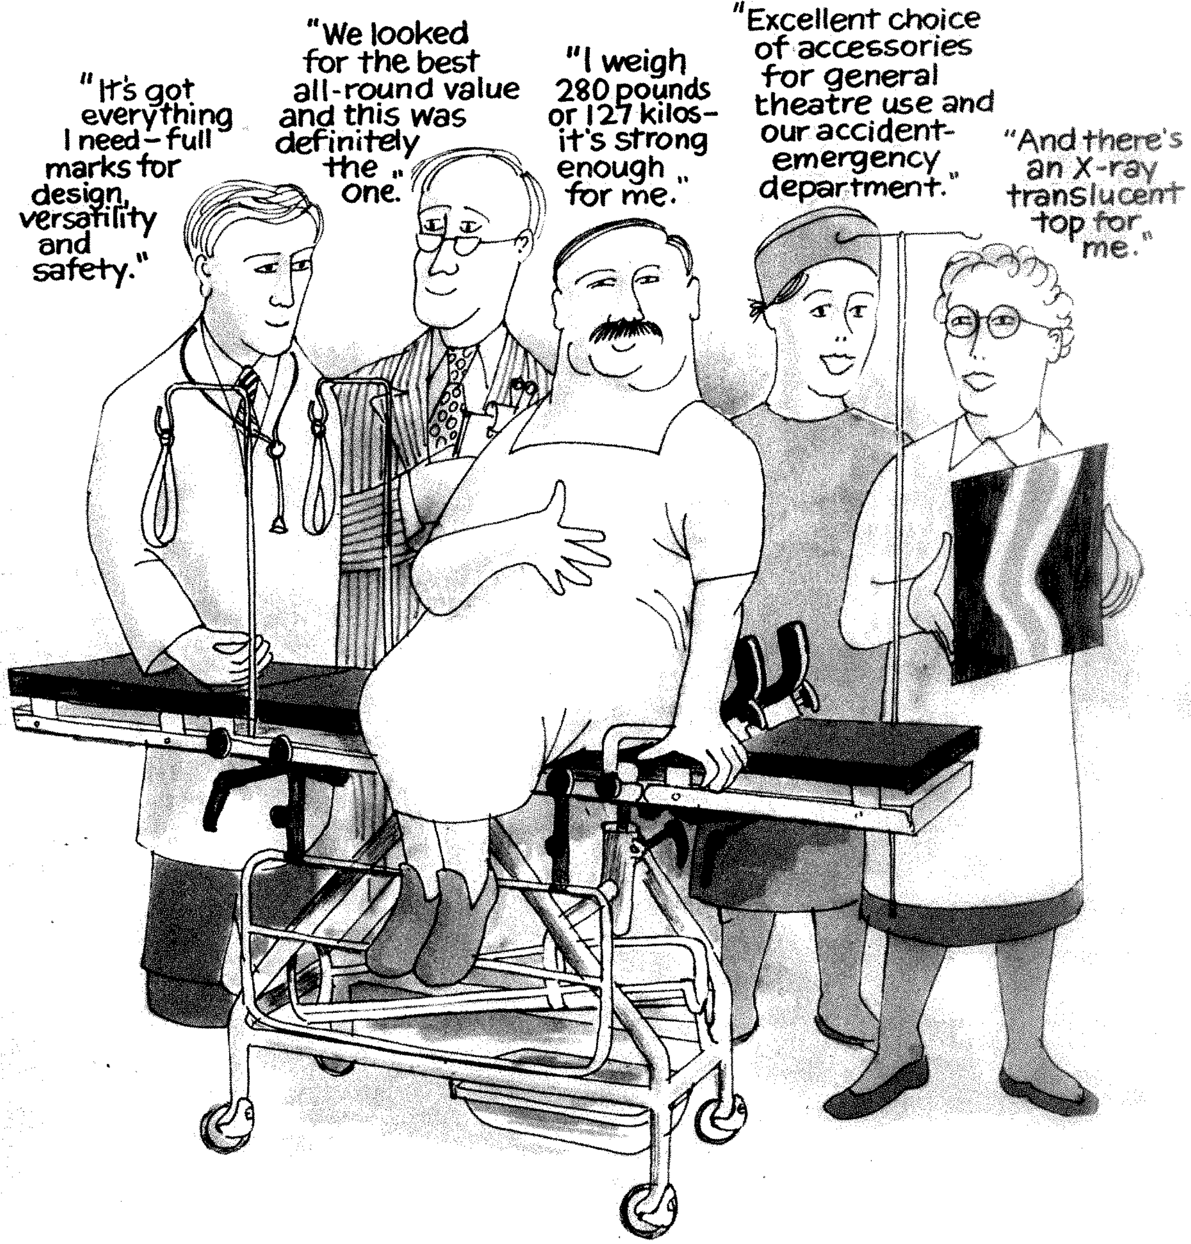
The results of this study show clearly that diazoxide is very effective in preventing hypoglycaemic episodes in patients with an insulinoma. There were no failures of treatment in the 21 patients in this series to whom it was administered: 7 patients were successfully maintained on this drug for periods of up to 12 years with no untoward late complications. In the early stages of administration of the drug, however, its effects must be observed carefully, both to adjust the dosage correctly and to check that it is not causing excessive fluid retention, a complication which necessitated withdrawal of the drug in 2 of our patients. This fluid retention is secondary to sodium retention, probably caused by increased sodium and water reabsorption in the proximal tubules as a consequence of the vasodilatory action of the drug (Pohl et al., 1972). The long term administration of diazoxide is a valuable alternative to removal of the tumour in those few patients in whom an operation is, for any reason, contraindicated. In addition to this clear-cut indication for its use, we believe that the patient's response to diazoxide should be assessed before operation in all cases, unless the site of the tumour has been clearly demonstrated before operation (*see below*).

In most patients with an insulinoma the definitive treatment is to perform an operation to identify and remove the tumour. Usually the tumour can be identified without great difficulty, but in some patients it may be impossible to locate it at operation. With this in mind, it is usually recommended that coeliac axis arteriography should be performed before operation in an attempt to demonstrate the tumour. Using a special technique involving selective injection of the individual arteries of the pancreas, Clouse and his colleagues (1977) demonstrated 8 of 10 tumours, but by the use of the conventional techniques of injection into superior mesenteric and coeliac vessels the success rate is only some 40–45 per cent (Harrison et al., 1973; Robins et al., 1973; Fulton et al., 1975), and is influenced by the size of the tumour. In assessing the significance of these results it must be borne in mind that the great majority of tumours can be detected at operation, and the crucial question to be answered is whether angiography can locate those tumours, usually small, which the surgeon is unable to palpate. It was with this consideration in mind that the study reported here was undertaken. In the event, in 3 patients the surgeon was unable to detect a tumour at operation, and in none did the angiogram give information enabling the tumour to be removed. Angiography was performed in a further 10 patients, in all of whom the tumour was detected at operation without undue difficulty. In 6 of these the tumour was correctly located by angiography, in 3 no tumour was shown and in the last patient the angiogram suggested a tumour in the head of the pancreas whereas at operation it was found to be in the tail.

We believe that this study casts serious doubt on the value of coeliac axis angiography in the localization of insulinomas. It is true that in about half the patients it will give clear guidance to the surgeon as to where he can expect to find the tumour, but even then the remainder of the pancreas will require careful examination to exclude a second tumour. Our study provides no evidence that the examination provides critical information about the site of the tumour in those patients in which it is most needed. Harrison et al. (1973) state that in 2 patients the arteriogram located a tumour that they could not palpate, but beyond this we can find no evidence from the literature that this is a frequent occurrence. In our opinion, the value of the information to be gained from conventional coeliac axis angiography does not justify the discomfort to the patient.

If no tumour can be found at operation the conventional surgical treatment is to perform a blind distal pancreatectomy. In a previous paper (Mengoli

Good reasons for choosing the Seward minor operating table



"It's got everything I need – full marks for design, versatility and safety."
"We looked for the best all-round value and this was definitely the one."
"I weigh 280 pounds or 127 kilos – it's strong enough for me."
"Excellent choice of accessories for general theatre use and our accident-emergency department."
"And there's an X-ray translucent top for me."

Hospitals in many parts of the world have chosen the Seward minor operating table. Because it has so many advantages — at a very competitive price . . .
Superb design quality — with stainless steel table-top and side rails.
Safety for the patient — instant tilt release into Trendelenberg and reverse Trendelenberg positions. Easily adjustable head and foot sections.
Accessories — wide range available from Seward.

Strong, handsomely styled, easy to keep clean. The ideal operating table for many surgical procedures, accident, casualty and outpatient departments. Send now for full details and a price list.

Debrisan beads
magnified x30
blue transmitted and
red incident light.

Creating the healing environment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing, such as bacteria and wound debris.

Pain, oedema and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast.

Use Debrisan on all moist suppurating wounds such as pressure sores and leg ulcers.

Patients can enjoy the benefits of the healing environment of the future. Today.

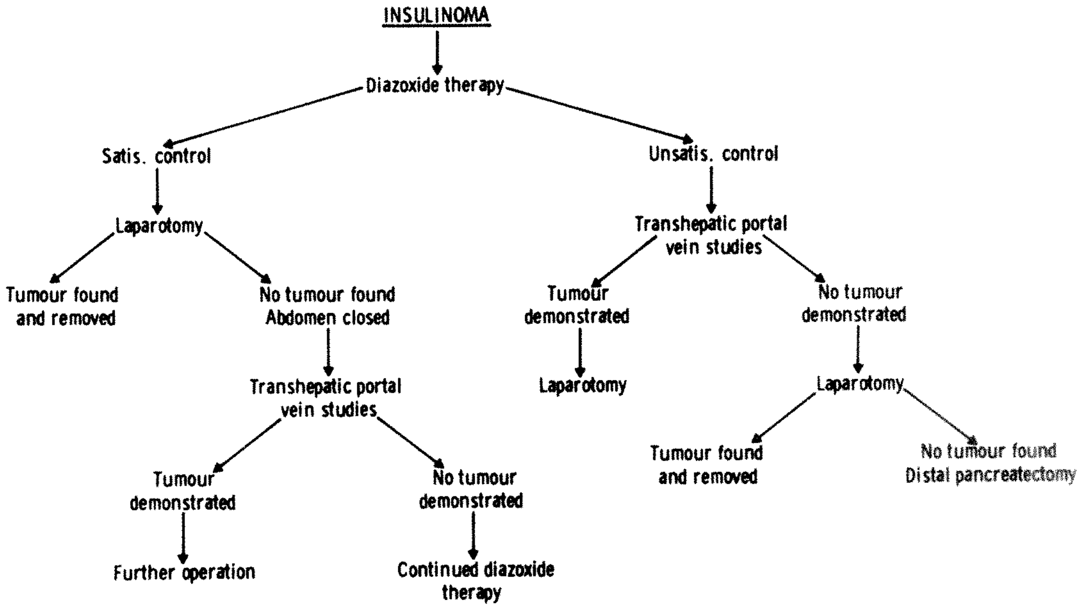

Fig. 3. Scheme for the management of patients with an insulinoma.

and Le Quesne, 1967) we drew attention to the fact that this procedure failed to remove the tumour in three-quarters of the patients on whom it was performed. In the light of this finding we suggested that, if the patient's hypoglycaemia could be controlled by diazoxide, this operation should not be performed, but the abdomen closed and the tumour sought for again at a second operation a year or more later by which time the tumour might have increased in size sufficiently to make its presence apparent.

This idea that, with the passage of time, the tumour will increase in size significantly would appear to be wrong. In a review of 542 cases of insulinoma, Stefanini et al. (1974) could find no evidence of a relationship between length of history and size of the tumour. Furthermore, in only 35 per cent of 168 patients undergoing a second operation for an occult tumour was the tumour identified at a subsequent operation, the remaining 65 per cent of the patients requiring a further blind resection to remove the tumour. Stefanini and his colleagues recommend that, if a tumour cannot be found at the initial operation, the correct procedure is to perform 'a progressive excision of the head of the pancreas from left to right guided by immediate pathological examination of the removed specimen, and by continuous measurement of the blood sugar concentration'. Bearing in mind that the studies of both Mengoli and Le Quesne (1967) and Stefanini et al. (1974) show that the majority of occult tumours are in the head of the pancreas, the implementation of this policy must result, in many of these patients, in the removal of a major portion of the pancreas, with its unavoidable consequences of both exocrine and endocrine insufficiency. Furthermore, it is by no means clear that continuous estimation of the blood sugar concentration can be relied upon to indicate that the tumour has been removed (Harrison et al., 1973).

The development of the new techniques of tumour localization by percutaneous transhepatic catheterization of the portal vein and possibly by ultrasound may well make obsolete this crude operation of blind distal resection of pancreatic tissue. The localization of an insulin tumour by percutaneous transhepatic catheterization of the splenic and portal veins was first described by Ingemansson et al. in 1975, and in 1977 Ingemansson et al. reported the localization of islet-cell hyperplasia in the tail of the pancreas by this technique. In 1978 Turner et al. reported 2 further patients in whom the tumour was successfully located before operation by this technique (one of these patients being *Case* 18 from this series). In addition, they described a modification of this technique in which the splenic vein is catheterized at operation and the blood samples analysed by a special rapid technique which gives the results of insulin assay in 50 min. Using this technique, which depends upon the same principle as the percutaneous preoperative examination, they successfully located 7 of 8 tumours. In the current series, a preoperative examination was carried out in 3 patients in addition to *Case* 18 (previously reported by Turner et al., 1978), and the tumour was located in 2. In the patient in whom the examination failed, there was evidence suggesting that the tumour only secreted intermittently. This evidence suggests that this technique is the most accurate available method for the localization of an insulinoma. In addition, our experience with 2 patients suggests that ultrasound may be a valuable technique for localizing these tumours.

Clearly, further experience is required before the exact place of catheterization of the portal venous system in the management of patients with an insulinoma can be defined. Such experience may in fact show that transhepatic catheterization should be performed in all patients before operation, but there is to date insufficient evidence to justify this conclusion. Furthermore, it is unlikely that the peroperative technique, which depends upon a very specialized technique of insulin assay, will ever be widely applicable. We believe, however, that the evidence at present available, together with the accumulated experience with the use of diazoxide, clearly indicates that, provided it is known that the patient's symptoms can be controlled safely with this drug, no patient should be submitted to blind distal resection without a prior portal vein catheter study. A scheme of management, based on the preoperative administration of diazoxide and designed to reduce to the minimum the need to perform a blind resection, is set out in *Fig*. 3. A similar scheme, based on the use of arteriography before operation and portal vein studies on the operating table, has been proposed by Turner et al. (1978).

Acknowledgements

It is a pleasure to acknowledge our gratitude to our colleagues in the Department of Radiology who carried out the arteriographic studies, and we are particularly indebted to Dr M. Raphael, who performed two of the percutaneous transhepatic splenic vein catheter studies.

A new look at the arterial supply of the bile duct in man and its surgical implications

J. M. A. NORTHOVER AND JOHN TERBLANCHE*

SUMMARY

The blood supply of the human bile duct has been re-evaluated using high resolution resin casts prepared from 24 fresh human cadavers. The refined technique used yielded casts of all vessels, including capillaries, and produced a clear picture of the blood supply of the human bile duct for the first time. The arterial supply of the supraduodenal duct was shown to be axial, with the main vessels, which have been named the 3 o'clock and 9 o'clock arteries, running along the lateral borders. The retroportal artery, which has not been described by previous workers, was present in all complete casts and was a major source of the axial blood supply to the supraduodenal duct in 32 per cent of them.

The major importance of this new knowledge of bile duct blood supply may well lie in the understanding of the aetiology of postoperative bile duct strictures and in their prevention. An explanation is proposed for the long strictures sometimes seen after minimal surgical trauma to the bile duct, based on damage to the small vessels supplying the duct; guidelines to prevent such damage are presented. Ischaemia of the bile duct may also explain some of the biliary problems that have followed human liver transplantation and other procedures involving biliary anastomosis, such as Whipple's operation.

THE arterial supply of the bile duct is a neglected subject, despite the large amount of biliary surgery being performed today. Textbooks of surgery and anatomy give it little attention, while the few publications on the subject differ widely in their conclusions.

The precise pathogenesis of postoperative bile duct strictures is as yet not fully explained. The generally held view is that operative trauma to the ducts is the main cause, but the mechanism whereby reputedly minimal surgical trauma can lead to almost total disappearance of the extrahepatic bile ducts in some patients remains a matter for speculation. Major interference with bile duct blood supply may be an important factor (Appleby, 1959).

Biliary complications remain a major stumbling block to progress in human liver transplantation (Calne, 1977). It has been suggested that poor blood supply to the donor bile duct may be responsible (Calne, 1972). The present anatomical study was initiated to investigate this problem. The potential importance of bile duct blood supply in the pathogenesis of bile duct strictures only became evident during the course of the study.

Materials and methods

Anatomical specimens were collected from 24 human cadavers within 12 h of death: all were previously fit adults who had died of non-abdominal trauma. A resin casting technique was used based on that of Tompsett (1970) but extended to allow casting of all vessels down to capillary size (Northover et al., 1979).

After maceration of the tissue in acid, dissection of the resin casts themselves was carried out. Extensive photography and, in some cases, scanning electron microscopy were employed to record the blood supply of the bile duct in each cast.

Results

The cast

Because total vascular replication, including the capillary bed, was achieved using this technique, the perfused organs were replaced by microvascular casts closely resembling the original organs (*Fig.* 1*a*). Thus, for instance, the duodenal cast could be opened to reveal that the mucosal villi were faithfully represented by resin casts of their capillaries. The same degree of resolution was achieved with the bile duct, where the mucosal capillary cast was well demonstrated by scanning electron microscopy (*Fig.* 2).

Major vessel anatomy

Although most textbooks describe a pattern of major arteries as shown in *Fig.* 3, this precise configuration was seen in only 2 (8 per cent) of the specimens in this series. This accords with the experience of previous workers, who have noted great anatomical variability in this region (Flint, 1923; Daseler et al., 1947).

Arteries supplying the duct

Twenty-one casts were of sufficient quality to allow definitive evaluation of the arterial supply of the bile duct. To facilitate description of its blood supply the duct has been subdivided into three segments, namely hilar (right and left hepatic ducts), supraduodenal (common hepatic duct and upper common bile duct) and retropancreatic (lower common bile duct). The supply of the supraduodenal duct will be described in detail as it is surgically the most important segment.

Supraduodenal duct: The supply of this segment was essentially axial, i.e. most vessels to the supraduodenal

Table I: MAJOR ARTERIES SUPPLYING BRANCHES TO THE SUPRADUODENAL BILE DUCT IN 21 CASTS

Artery	Casts in which the bile duct received arteries from this source	
	Total	%
Retroduodenal artery and main branches	17	81·0
Right hepatic artery	16	76·2
Cystic artery	11	52·4
Gastroduodenal artery and main branches*	9	42·9
Retroportal artery (arising from coeliac axis)	9	42·9
Retroportal artery (arising from superior mesenteric artery)	9	42·9
Left hepatic artery	5	23.8
Common hepatic artery	3	14.3
Others	5	23·8

* Excluding its most important branch, the retroduodenal artery.

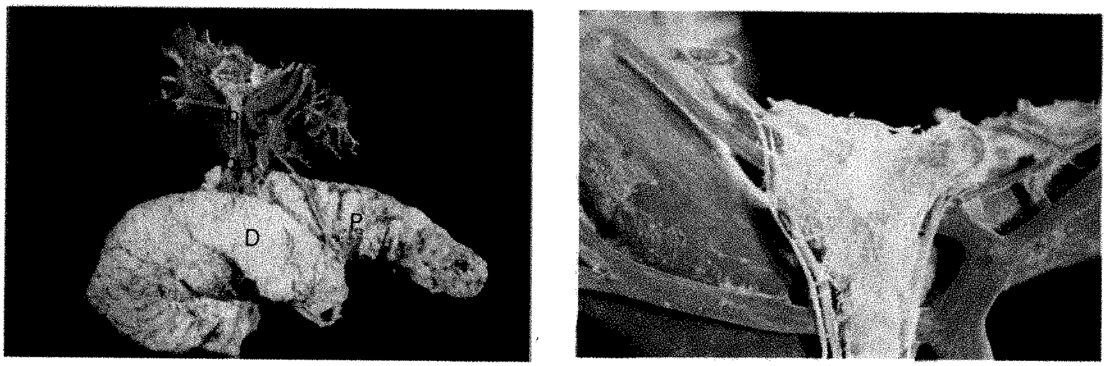

Fig. 1. *a*, A resin cast at an early stage of dissection. Note that there is no tissue present in this specimen. Casts of the gallbladder, cystic duct, central portion of the supraduodenal duct and most of the liver have been removed. The 3 o'clock and 9 o'clock arteries and veins (arrowed) are seen at the lateral borders of the supraduodenal duct (b). *b*, Close-up view of the upper common hepatic duct cast to show precise relations of the 3 o'clock and 9 o'clock vessels (the veins appear mauve due to slight transcapillary passage of red resin). A series of small arteries and veins leaves these axial vessels to form the plexus around the duct. In this specimen the 3 o'clock and 9 o'clock vessels extend to a higher level than usual. (P, pancreas; D, duodenum.)

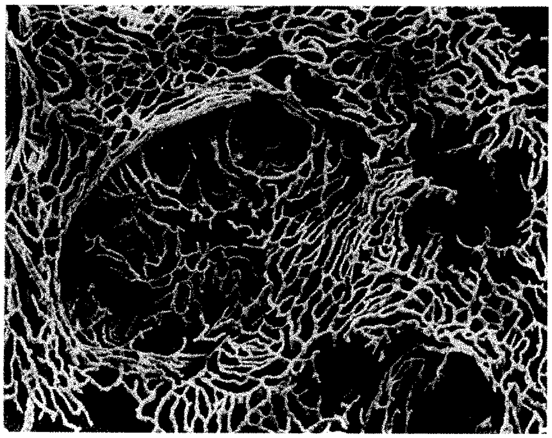

Fig. 2. A scanning electron micrograph of a resin cast of the bile duct mucosal capillaries. A 1-mm oval pit, at left centre, lined by capillaries, is typical of those seen in the mucosa of the bile duct. (×40.)

duct arose from named arteries related to its upper and lower ends (*Table I*). On average, 8 small arteries, each about 0·3 mm in diameter, supplied the supraduodenal duct. The most important of these axial vessels ran along the lateral borders of the duct; as these vessels have not been adequately described or named previously we have called them the 3 o'clock and 9 o'clock arteries (*Figs.* 1, 3, 4). One or both of these arteries was present in all specimens. Many of the other vessels supplying the duct arose from the retroduodenal and gastroduodenal arteries below (*Fig.* 5). On average, 60 per cent of vessels reaching the supraduodenal duct ran upwards from the major vessels below; 38 per cent of vessels ran downwards from the right hepatic and other arteries, while only 2 per cent of the supply was non-axial arising from the trunk of the common hepatic artery (*Fig.* 6, *Table II*).

An important source of supply to the supraduodenal duct was a vessel not described by previous workers, which has been named the retroportal artery (Northover and Terblanche, 1978). This vessel, which was present in all the casts, arose posteriorly from either the coeliac axis or superior mesenteric artery close to their origin from the aorta (*Table III*). From its origin it passed to the right, behind the portal vein and on to the back of the head of the pancreas to reach the lower end of the supraduodenal duct (*Figs.* 7, 8). From this point the further course of the artery varied. In about half the casts the artery terminated by joining the retroduodenal artery close to the lower end of the supraduodenal duct (*Fig.* 7); in these specimens small branches from the trunk of the retroportal artery passed on to the posterior surface of the duct—this has been designated the type I pattern. In a third of the casts the type II pattern

Table II: RELATIVE PROPORTIONS OF TOTAL ARTERIAL SUPPLY OF THE SUPRADUODENAL BILE DUCT FROM VARIOUS SOURCES, EXPRESSED AS PERCENTAGES OF TOTAL SUPPLY (DERIVED FROM SUMMATED DATA IN 21 CASTS)

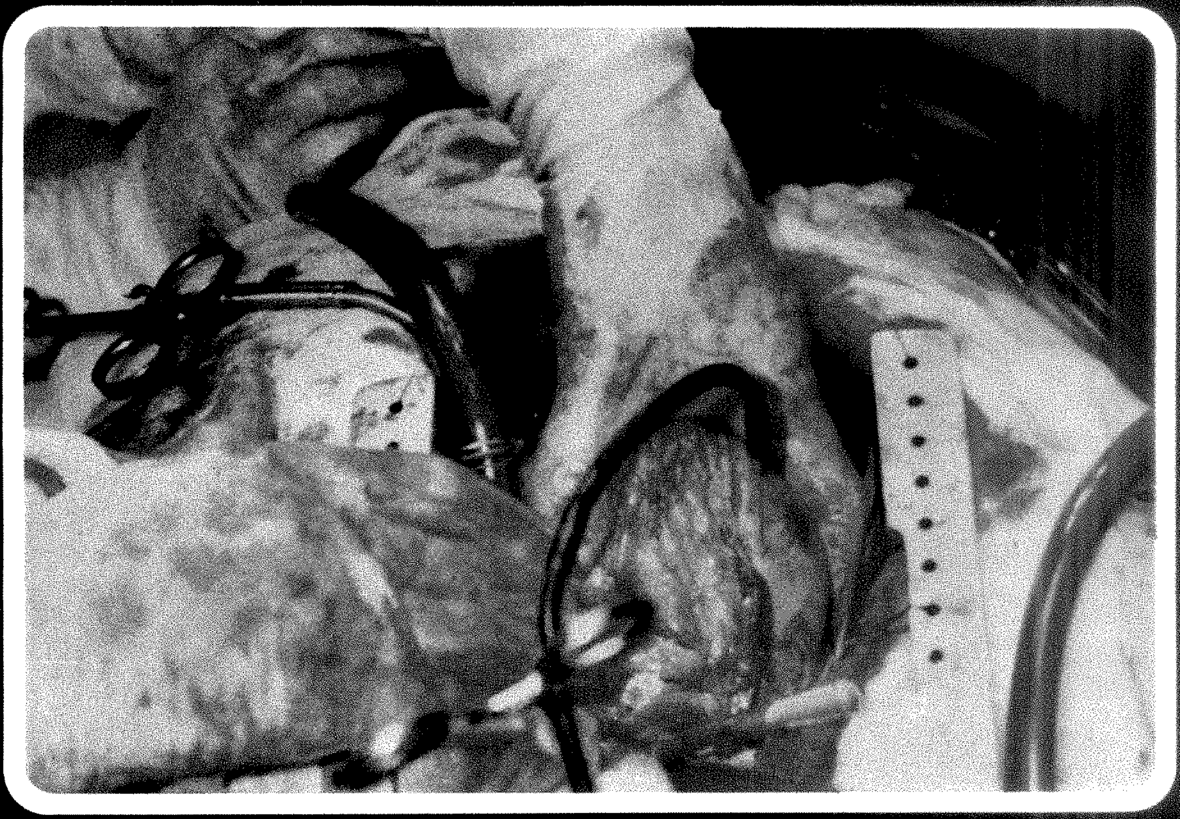
Direction of supply	Artery of origin	% of total arterial supply	
From below	Retroduodenal artery	26.9	60·1
	Retroportal artery	15·8	
	Gastroduodenal artery	9·9	
	Others	7·5	
From above	Right hepatic artery	25·5	38·0
	Cystic artery	7·5	
	Left hepatic artery	3·1	
	Others	1·9	
From left	Common hepatic artery	1·9	1·9

Table III: ORIGIN OF RETROPORTAL ARTERY IN 20 CASTS

Artery of origin	No. of casts
Coeliac axis and major branches	9
Superior mesenteric artery and major branches	9
Joint origin from coeliac axis and superior mesenteric artery	1
Retroportal artery replaced by aberrant right hepatic artery arising from superior mesenteric artery	1

Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted 'Magnapen' containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post operative chest and wound
Dosage: Adult: 1 capsule or 10ml syrup or 1 vial qid. Children (2-10 years) [illegible] adult dose. Under 2 years [illegible] adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL 0038/5001-5009
Contra-indications: Penicillin hypersensitivity; ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product

Basic N.H.S. Prices [illegible]
Capsules 500mg £18.06 (100) [illegible]
Syrup 250mg per 5ml £1.18 (100ml) [illegible]
Vials 500mg £7.48 (10 vials) [illegible]

Magnapen is available to hospitals [illegible] dependent upon estimated usage.

Further information on Magnapen [illegible] the company.

Magnapen, BRL and the [illegible] trade marks.

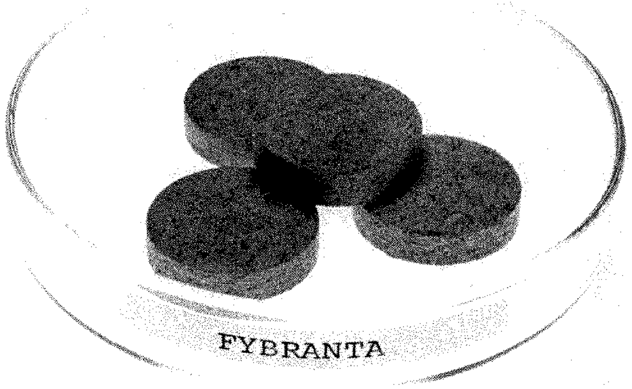
FYBRANTA
cereal fibre



The only fibre
that does all it should

Fybranta contains unprocessed cereal fibre which has been clinically proved more effective than other widely used fibre treatments. Only cereal fibre significantly reduced transit time[1,2] and also lowered intraluminal pressure when tested against other substances[2]. In addition, Fybranta was shown to be effective in increasing stool weight[1].

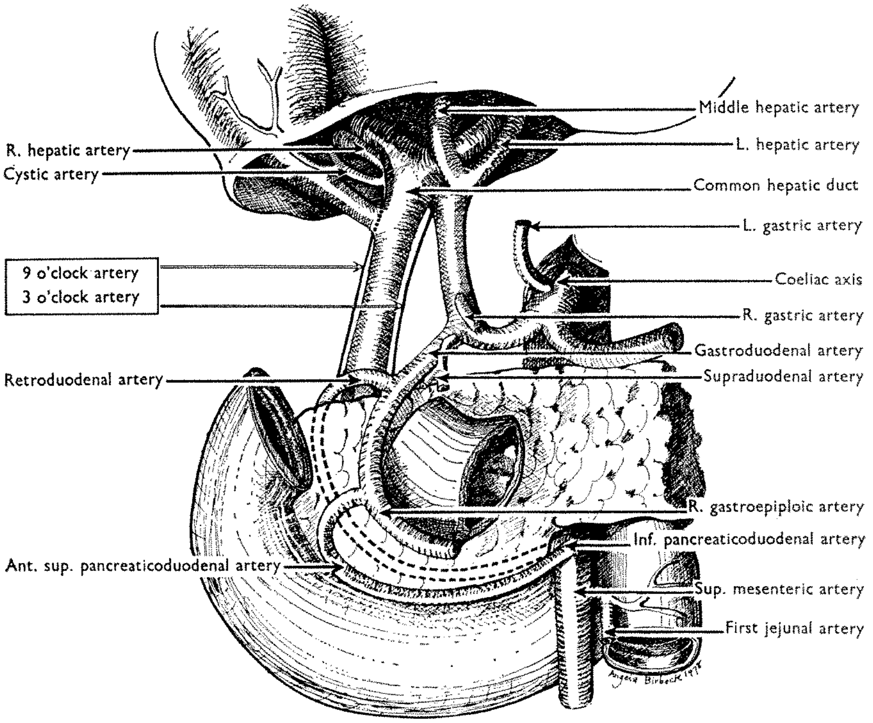

Fig. 3. The major arteries related to the supraduodenal bile duct. Part of the duodenum has been omitted to reveal the origin of the retroduodenal artery from the gastroduodenal artery.

prevailed (*Fig.* 8), in which the retroportal artery itself passed upwards on the back of the supraduodenal duct and joined the right hepatic artery behind the common hepatic duct. *En route* it gave branches which joined the pericholedochal plexus. Unlike the type I retroportal artery, which supplied the supraduodenal duct solely from below, the type II retroportal artery played a major role in supplying the duct from above by virtue of its truncal connection with the right hepatic artery.

Hilar ducts: These ducts were usually closely related to the left and right hepatic arteries and received a copious supply of small arteries from these trunks, forming a rich network on the surface of the ducts, in continuity with the plexus around the supraduodenal duct. In some casts the 3 o'clock and 9 o'clock arteries extended upwards to contribute to the supply of the hilar ducts (*Fig.* 1).

Retropancreatic duct: The pattern of supply of this segment resembled that of the hilar ducts in that the duct was closely related to a parallel major artery, i.e. the retroduodenal artery, which provided multiple small vessels running around the duct to form a mural plexus (*Fig.* 9).

Intramural arteries of the bile duct

The axial arteries of the supraduodenal duct (3 o'clock, 9 o'clock and type II retroportal arteries) and the many small vessels surrounding the hilar and retropancreatic ducts gave rise to multiple arteriolar branches which formed a free anastomosis within the wall of the bile duct. No end-arteries were noted in this series. The arteriolar plexus in turn gave rise to the capillary plexus. Using the scanning electron microscope, the mucosal capillary plexus was clearly demonstrated to be made up of vessels 10–16 μm in diameter (*Fig.* 2).

Discussion

A clear understanding of the blood supply of the human bile duct, which has hitherto not been available, may provide important clues to the pathogenesis of bile duct strictures and may explain the high incidence of biliary leakage and sludge formation when direct bile duct anastomosis is employed in human liver transplantation (McMaster et al., 1978).

The eight papers on the arterial supply of the bile duct which have appeared in the world literature of the past 30 years differ fundamentally in their conclusions (Douglass and Cutter, 1948; Shapiro and Robillard, 1948; Henley, 1955; Munkácsi and Siklós, 1960; Michels, 1962; Parke et al., 1963; Ranga and Andronescu, 1966; Pförringer, 1971). These differences have major surgical implications. On the one hand, Shapiro and Robillard (1948) suggest that the duct is supplied by a few end-arteries, damage to any of which would surely lead to stricture and anastomotic leakage, while at the other extreme Douglass and Cutter (1948) found an abundant plexus around the duct, so that nothing short of skeletonization would critically damage the blood supply. Such disparate conclusions must raise doubts about the reliability of the techniques used in some of these studies. The technique employed in the present study proved highly satisfactory. The use of fresh cadavers minimized small vessel loss by autolysis, while the casting technique produced organ replicas which lent themselves easily to microdissection and scanning electron microscopy.

While previous studies have tried simply to determine which major arteries supply small vessels

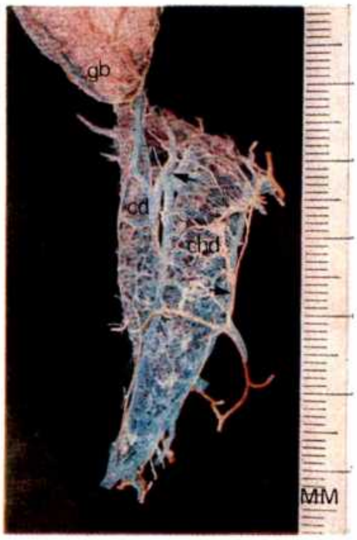

Fig. 4. An isolated cast of the supraduodenal and cystic ducts. The 3 o'clock and 9 o'clock arteries and veins (arrowed) are seen at the borders of the supraduodenal duct; attempts to flush-tie the cystic duct (cd) could damage the 9 o'clock vessels. Small arteries are seen joining the main axial vessels from above and below. Note the millimetre scale on the right. (gb, gall bladder; chd, common hepatic duct.)

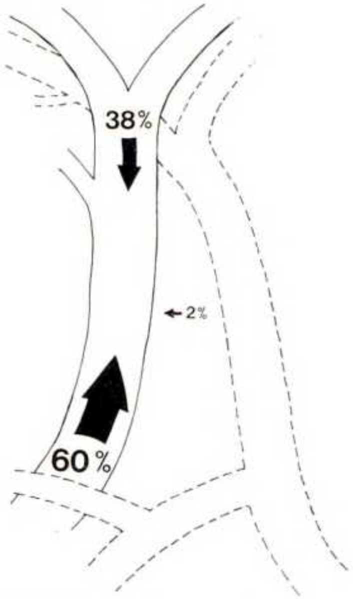

Fig. 6. Mean percentage (to the nearest whole number) of supraduodenal bile duct arterial supply from various directions. Note that the vast majority of vessels reach the duct in axial fashion.

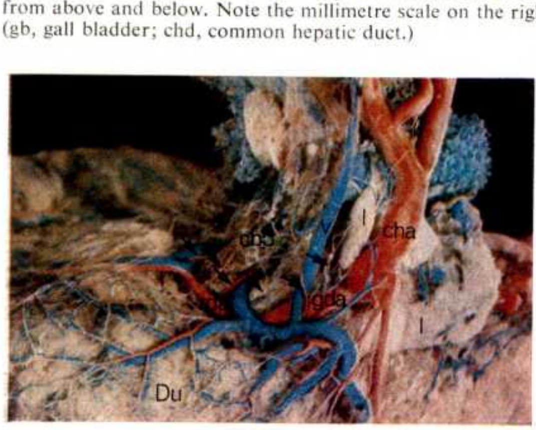

Fig. 5. Anterior view of structures in the free edge of the lesser omentum: the common bile duct (cbd) and common hepatic artery (cha) lie in front of the portal vein which is almost hidden from view. The first part of the duodenum (Du) is seen below, with the gastroduodenal artery (gda) and its retroduodenal branch (rda) lying behind it. These two arteries give six axial arteries (arrowed) to the supraduodenal duct. A very large 3 o'clock vein (v) is present. Lymph node capillary casts (l) surround the common hepatic artery.

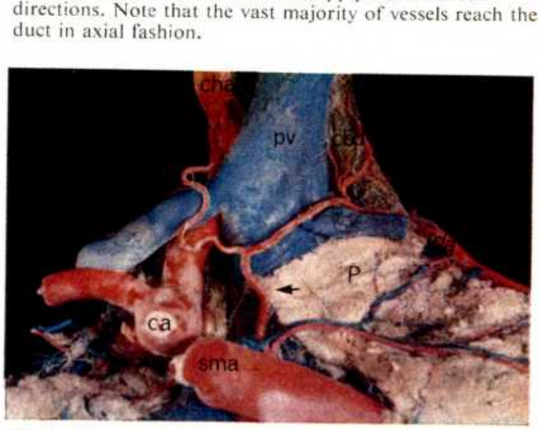

Fig. 7. Posterior view of a cast to show a type I retroportal artery. The origins of the coeliac axis (ca) and superior mesenteric artery (sma) can be seen below the splenic vein. The retroportal artery (arrowed) arises from the superior mesenteric artery and crosses the back of the portal vein (pv); in this cast it gives off a branch which joins the common hepatic artery (cha). The retroportal artery passes between the portal vein and the supraduodenal bile duct (cbd) to join the retroduodenal artery (rda) although the junction is hidden from view by the duct. As it passes the duct it gives off several branches which join the periductal plexus. Note that the duodenal cast has been removed. (P, head of the pancreas.)

to the duct, the present study has also attempted to quantify the supply from these various sources. It has shown that the axial supply to the supraduodenal duct is mainly from below; the retroduodenal artery, a vessel adequately described as late as 1941 (Edwards, 1941), provides the bulk of supply from this direction. The right hepatic artery contributes most of the supply from above.

The 3 o'clock and 9 o'clock arteries have not been fully described before, although they are almost always present, and readily damaged during surgical dissection. The 9 o'clock artery, at the right border of the duct, conforms with the marginal anastomotic loop noted by Douglass and Cutter (1948) and Parke et al. (1963).

The retroportal artery is another important vessel, though it has not been noted previously, perhaps because of its posterior position. Douglass and Cutter (1948) described one specimen in which an artery arose from the coeliac axis and passed through the substance of the pancreas to supply the distal common duct. This may well have been the first report of the retroportal artery, although it was not recognized as

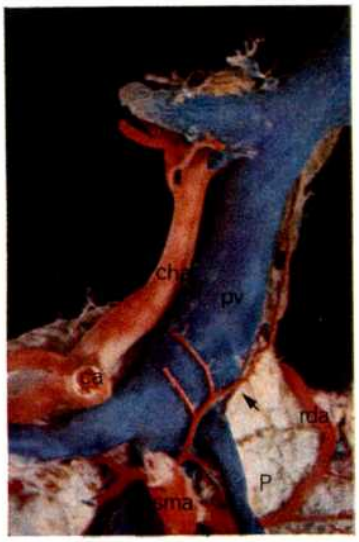

Fig. 8. Posterior view of a cast to show a type II retroportal artery. The coeliac axis (ca) and superior mesenteric artery (sma) are seen above and below the splenic vein. The retroportal artery (arrowed) arises from the superior mesenteric artery and passes across the back of the portal vein (pv) to reach the posterior surface of the supraduodenal bile duct (parts of which have been removed). The artery ascends to join the right hepatic artery, hidden by the right branch of the portal vein. Note that the duodenal cast has been removed. (P, head of the pancreas.)

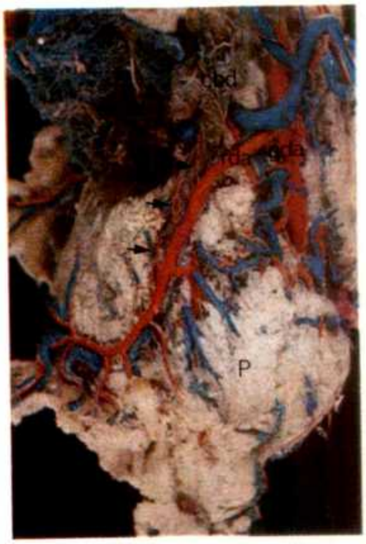

Fig. 9. To show the supply of the retropancreatic duct by the retroduodenal artery. The convex right lateral surface of the head of the pancreas (P), with the duodenum removed, is seen in the centre. The retroduodenal artery (rda) arises from the gastroduodenal artery (gda) in front of the pancreas and passes to the posterior surface of the latter to come into close contact with the retropancreatic bile duct (cbd), which it supplies with several arteries (arrowed).

such at the time. The present study has shown this vessel to be constant in occurrence, though varying in its precise origin, its mode of termination and its contribution to the axial supply of the supraduodenal duct.

Bile duct strictures have been variously attributed to the necrotizing effect of bile, to ischaemia or to a combination of these factors. In 1950, Douglass et al. demonstrated that the marked fibrotic reaction occurring at a healing bile duct anastomosis in the dog was avoided if the anastomosis was protected by proximal bile diversion. Later Rains (1959) confirmed the propensity for bile to induce fibrosis. Cameron and Hou (1962), however, felt that ischaemia alone was the cause of duct stricture—they were able to induce this lesion by cross-clamping the bile duct of the guinea-pig for 1 min, thus inducing temporary segmental ischaemia. Appleby (1959) linked the two factors by suggesting that bile destroyed only ischaemic tissue, leaving normal tissue undamaged. Carlson et al. (1977) have recently shed light on the action of bile on duct tissue. In a study in which they ligated the bile duct in dogs, they showed that bile gained access to mural collagen via mucosal defects which appeared proximal to the site of the ligature. Bile then caused a disturbance in the cohesive forces in the collagenous matrix of the duct wall, leading to rapid collagen turnover and, ultimately, thickening of the duct wall.

Based on the anatomical data revealed in the present study and the findings of the workers mentioned above, we suggest that postoperative bile duct strictures may arise in the following manner. Ischaemia, whether caused directly by accidental duct clamping or indirectly by trauma to the bile duct blood supply, might damage ductal mucosa sufficiently to render it permeable to bile, which would then act on ischaemic tissue within the wall to induce inflammation and fibrosis. Oedema accompanying such a reaction might even occlude adjacent parts of the choledochal arterial plexus, as these vessels are only 0·3 mm or less in diameter. This would produce further ischaemia and lead to a spreading cycle of collagen breakdown and fibrosis until a large part of the duct has been destroyed. The supraduodenal duct is the area most likely to be damaged by this process, as its blood supply is more vulnerable than that of the hilar and retropancreatic segments.

The clearer understanding of the blood supply of the bile duct which has emerged as a result of this study has made it possible to define guidelines which should help to avoid damage to the blood supply of the supraduodenal duct during routine biliary surgery and hence, perhaps, to prevent some strictures. Dissection around the common bile duct should be restricted to that which is absolutely necessary for the particular procedure being undertaken; it should be especially avoided at the edges of the duct to preserve the 3 o'clock and 9 o'clock arteries and their branches to the choledochal plexus. Where possible, the cystic duct should not be divided flush with the common bile duct to avoid damage to the 9 o'clock vessels, and the cystic artery should be divided near the gallbladder to preserve its branches to the common duct. Dissection in the groove between the supraduodenal bile duct and the first part of the duodenum endangers the retroduodenal artery and its copious branches to the duct at this point. Finally, in performing Kocher's manoeuvre, the thin fibrous layer on the back of the head of the pancreas and portal vein should be left intact to preserve the retroportal artery.

Another important area in which a better understanding of bile duct blood supply should be of assistance is the field of biliary anastomosis. The implications in the bile duct reconstruction used in liver transplantation have been discussed elsewhere (Northover and Terblanche, 1978). The unacceptably high incidence of anastomotic complications that follows direct anastomosis of donor to recipient common bile duct in man (Williams et al., 1973; Starzl et al., 1976) stands in stark comparison with the uniformly good results obtained using the same anastomosis for liver transplantation in the pig and baboon; this difference may well be related to species differences in bile duct blood supply (Northover and Terblanche, 1978). In addition, it would appear that human liver transplant specimens with a type II retroportal artery have a better vascularized donor duct than those with the type I retroportal artery. McMaster has recently shown that the biliary sludge which so often complicates human liver transplantation, and which is usually found adhering exclusively to the wall of the donor duct, consists mainly of necrotic collagen (McMaster et al., 1978). This might well suggest that the operative procedure as it stands produces an ischaemic donor bile duct, which is likely to lead to healing problems. It has been suggested that most of the donor duct be sacrified, necessitating division at high donor common hepatic duct level, in order to provide a better perfused ductal remnant for successful anastomosis (Northover and Terblanche, 1978).

Biliary anastomotic leakage and stricture have been reported to be quite common after pancreaticoduodenectomy (Mongé et al., 1964; Gilsdorf and Spanos, 1973). This may be another situation in which compromise of the bile duct blood supply has led to serious postoperative complications which may be avoidable in the light of a better knowledge of the blood supply to the bile duct.

A comparison of xenon-133 clearance with electromagnetic flowmeters and an indicator dilution method for the measurement of liver blood flow

JOANNA THORNE, R. BENNETT, R. SHIELDS, J. JOHNSON AND I. TAYLOR*

SUMMARY

Measurement of liver blood flow has been carried out by three different methods in 14 dogs to assess the accuracy of xenon-133 clearance following portal vein injection.

Electromagnetic flowmetry with flow probes on the hepatic artery and portal vein resulted in a mean value of 121·9 ± 39·3 ml min^{-1} 100 g^{-1}. An indicator dilution study utilizing chromium-51-labelled red cells gave a mean value of 119·4 ± 31·4 ml min^{-1} 100 g^{-1} and the xenon-133 clearance following portal vein injection, 120·3 ± 33·8 ml min^{-1} 100 g^{-1}. One-way analysis of variance showed no statistically significant variation between these three groups. There was a close correlation between xenon-133 clearance and electromagnetic flowmetry and between xenon-133 clearance and the indicator dilution technique.

These data suggest that xenon-133 clearance following portal vein injection gives an accurate assessment of liver blood flow and this technique (as well as direct parenchymal injection) can be adapted for clinical use.

FOR several years the clearance of an inert radioactive gas has been used to measure blood flow through tissues. Recently this method, using xenon-133, has been adopted to determine hepatic blood flow (Birtch et al., 1967; Sherriff et al., 1977). The resulting clearance curves have a double exponential form, although recent work has suggested that only the initial fast component gives an indication of hepatic blood flow, while the slow component is due to extrahepatic sources (Darle, 1970; MacKenzie et al., 1976). Measurements of liver blood flow using the clearance of xenon-133 give an indication of nutritive perfusion and we have used this method in our studies on both normal liver and liver metastases (Sheriff et al., 1977).

Clearly it is important to ascertain that measurements obtained by clearance studies accurately reflect the flow throughout the whole liver and that the results obtained are comparable with those obtained by other methods. This study, carried out in the dog, compares the liver blood flow calculated from the clearance of xenon-133 with that derived from electromagnetic flowmeters and an indicator dilution technique. Clearance of xenon-133 was measured following injection into both the portal vein and the hepatic parenchyma. The technique of direct injection into the liver parenchyma has obvious clinical importance, since it is simple to perform and does not require access to either the portal vein or the hepatic artery. Previous reports have suggested that the technique is both reliable and reproducible (Gelin et al., 1968) but it has not been compared with the more conventional methods of blood flow measurement.

Materials and methods

Experiments were performed on 14 dogs (weighing between 15 and 20 kg). Anaesthesia was induced by intravenous injection of sodium pentobarbitone and, following endotracheal intubation, was maintained with nitrous oxide, oxygen and 0·5–1 per cent halothane. The dogs were ventilated in an open circuit. Saline solution was infused through the brachial vein.

Through a midline incision, the portal vein and hepatic artery were mobilized to ensure that at least 2 cm of each vessel were clearly visible. The portal vein was cannulated via the pancreatic vein.

The cranial mesenteric artery was cannulated via the femoral artery, and one hepatic vein, usually the left, was cannulated via the jugular vein.

Flow measurements

Electromagnetic flowmeter: Appropriate flow probes were attached around mobilized segments of the portal vein (above the junction with the pancreatic vein) and the hepatic artery. Care was taken to ensure that the probes fitted closely to the vessel without causing constriction (probes which are either too tight or too loose give false readings).

The probes were attached to a Biotronex Flowmeter (Model BL613 EZ–ZA) and flow in millilitres per minute through each vessel was read directly off the scale. Readings were taken at 2-min intervals. The results were expressed in ml/min for each vessel and in ml min^{-1} 100 g^{-1} wet weight of liver for the total hepatic blood flow.

Indicator dilution studies: The indicator used in these studies was autologous red blood cells, labelled with chromium-51 (^{51}Cr-RBCs). These were prepared according to the method of Wagner (1968) using 250 µCi of ^{51}Cr-sodium chromate in 15 ml of blank, autologous whole blood. The packed ^{51}Cr-RBCs were reconstituted to the original haematocrit of the dog with 0·9 per cent w/v saline. Then 2·7 ml of reconstituted blood was rapidly injected into the mesenteric artery through the cannula which was flushed through with 10 ml of saline. Immediately portal and hepatic venous blood samples were collected and collection continued at 1-s intervals on identical fraction collectors (LKB Redirac, modified) for 60 s. Aliquots of 0·4 ml were taken from the injection mixture to be used as a standard, and from each subsequent sample. These aliquots were counted for ^{51}Cr gamma activity on a Nuclear Chicago gamma counter (model no. 4233).

Xenon-133 studies: A collimated sodium iodide detector 2 in (5 cm) in diameter was positioned on a fixed stem so that the liver was in the field of view. Approximately 0·5 µCi of xenon-133 in 0·1–0·5 ml saline were injected into the portal vein cannula and flushed through with 10 ml saline. The clearance curve was recorded over a 10-min period on a pen recorder.

When residual activity had reached low levels, a further measurement of hepatic blood flow was obtained by direct parenchymal injection of xenon-133.

Liver function tests

The concentration of total protein, albumin, sodium, potassium and bilirubin was determined in the serum of all dogs. Serum activity of glutamic pyruvic transaminase, glutamic oxaloacetic transaminase, alkaline phosphatase and glutamic dehydrogenase was also determined at the commencement of the study and dogs with abnormal liver function tests were excluded.

At the completion of the study the liver was removed and weighed to permit the expression of all flow in terms of liver weight (as ml min^{-1} 100 g^{-1}).

Calculations of hepatic blood flow

Electromagnetic flowmeters: Flows for the portal vein and hepatic artery were read directly from the scale in ml/min and totalled to give hepatic blood flow.

Indicator dilution studies: Indicator dilution curves were constructed as graphs of outflow fraction × 10^3 against time where outflow fraction = (cpm/ml in sample)/(cpm/ml in standard). Portal and hepatic flow rates can be calculated directly from the area beneath the curves from the portal vein and hepatic vein respectively, from the formula:

$$\text{blood flow} = \frac{\text{cpm/ml standard}}{\text{(cpm/unit area)/unit time}} \times \text{area under curve.}$$

Xenon-133 clearance studies: The rate of disappearance of xenon-133, a rapidly diffusible gas, from a given tissue is dependent upon the blood flow through that tissue and the relative solubility of xenon-133 between the tissue and the blood (the partition coefficient). Thus, the clearance of the gas represents tissue (or nutritive) perfusion. The equation used to calculate tissue blood flow in ml min^{-1} 100 g^{-1} liver is blood flow $= k\lambda \times 100/\rho$, where k is the exponent of the exponential clearance curve (and is equal to $\ln 2/T_{\frac{1}{2}}$, where $T_{\frac{1}{2}}$ is the time taken for the liver activity to fall to half its initial value); λ is the partition coefficient for xenon, usually taken as 0·74 (Conn et al., 1961); and ρ is the density of liver tissue.

Results

Electromagnetic flowmetry

The mean values for total hepatic blood flow expressed in ml min^{-1} 100 g^{-1} are shown in *Table I*. These values varied from 78·8 to 200·0 ml min^{-1} 100 g^{-1} (mean 121·9 ± 39·3).

Indicator dilution studies

In 6 of the dogs studied, hepatic blood flow was measured by indicator dilution methods. A typical indicator dilution curve obtained from one of these dogs is shown in *Fig.* 1.

The values obtained by this method ranged from 84·3 to 189·3 ml min^{-1} 100 g^{-1} (mean 119·4 ± 31·4). These values are shown in *Table I*.

Xenon clearance

Portal vein injection: Liver blood flow values following intraportal injection were obtained in 12 dogs. In each dog a double exponential curve was obtained (*Fig.* 2). Liver blood flow was calculated by measuring the slope of the fast component.

A wide variation was observed between the dogs (range 68·2–193·4 ml min^{-1} 100 g^{-1}, mean 120·3 ± 33·8). The values obtained were compared with the simultaneously observed flowmeter and indicator dilution values and are shown in *Table I*.

Parenchymal injection: Values of liver blood flow following direct parenchymal injection were obtained in 8 dogs. The values obtained are shown in *Table I*. In one dog (dog 3, *see Table I*) a monoexponential clearance was obtained, but in the remainder the typical double exponential curve was apparent. The values obtained varied between 69·8 and 132·3 ml min^{-1} 100 g^{-1} (mean 89·7 ± 21·3).

Comparison of hepatic blood flows obtained by different methods

It can be seen that a very close correlation exists between the total hepatic blood flow measured by the clearance of a portal injection of xenon-133 and by the use of electromagnetic flowmeters ($r = 0·90$). The regression curve for these factors is shown in *Fig.* 3. There were also strong positive correlations between total hepatic blood flow measured by the indicator dilution technique and those measured by the use of electromagnetic flowmeters (*Fig.* 4) and the clearance of a portal injection of xenon-133 ($r = 0·94$ and 0·79 respectively). One-way analysis of variance shows no statistically significant variation between these three groups (degrees of freedom, 2·29; $F = 0·177$; $P < 0·05$).

All flow values are expressed as ml min^{-1} 100 g^{-1}.

Discussion

Measurement of liver blood flow by noting the clearance of xenon-133 following portal vein administration has been shown to be a useful technique both in animals (Darle et al., 1970) and in man (Sheriff et al., 1977). The clearance curve obtained is a double exponential, of which the initial fast component represents blood flow whereas the other components are probably extrahepatic in origin (MacKenzie et al., 1976; Leiberman et al., 1978). If this technique is to find a place in routine clinical assessment then it must be shown to compare favourably in reproducibility with other, more established techniques. This is particularly important since the counts obtained indicate clearance from, and therefore blood flow through, superficial tissue which may not necessarily be the same as total liver blood flow as measured by electromagnetic flowmetry and indicator dilution methods. These three methods of measurement of total hepatic blood flow depend on different physical principles.

Electromagnetic flowmeters measure changes in the electromagnetic field induced by, and directly proportional to, the flow of blood through a vessel. Flowmeters placed on the hepatic artery and portal vein give measures of portal venous and hepatic arterial flow and therefore of total liver blood flow.

The indicator dilution technique relies on the dilution of an inert indicator by the blood flowing through an organ. The blood flow is directly proportional to the degree of dilution of that indicator. Certain requirements have to be fulfilled for the use of any compound as an indicator in the measurement of hepatic blood flow (Reichman et al., 1958; Shoemaker et al., 1961; Huet et al., 1973): (*a*) the indicator must be conserved, i.e. not metabolized or excreted by the liver; (*b*) there must be no loss of indicator through extrahepatic shunts; (*c*) the indicator must be thoroughly mixed with blood before it reaches the sampling sites; (*d*) sampling must be of mixed venous blood; (*e*) intrahepatic circulation must be in a steady state.

These conditions are all fulfilled for the use of ^{51}Cr-RBCs in these experimental conditions. The injection of the indicator into the cranial mesenteric artery ensures thorough mixing in the mesenteric circulation (Huet et al., 1973), and sampling from the portal vein close to its bifurcation and from a large hepatic vein ensures that mixed venous blood is being sampled. Since this is so, the portal blood flow and total hepatic flow can be directly calculated from the areas under the portal vein curve and hepatic vein curve respectively.

The xenon-133 clearance technique measures the rate of removal of xenon-133 from a tissue by the passage of blood through it. The rate of clearance is proportional to the rate of flow through the tissue and can be used to measure regional or total blood flow directly in ml $\mathrm{min^{-1}}$ 100 $\mathrm{g^{-1}}$ of tissue. The measurement of flow in ml $\mathrm{min^{-1}}$ unit $\mathrm{weight^{-1}}$ eliminates the need for knowledge of liver weight and allows direct comparisons to be made between different subjects.

Total hepatic blood flow measured simultaneously by these three techniques gives values that are highly comparable. Since all three methods are based on different principles it would therefore seem that they accurately measure blood flow. Of the three methods, injection of xenon-133 into the portal vein is preferable in the clinical situation since it is rapid (taking a total of about 15 min) and relatively simple. The technique employing indicator dilution curves requires less specialized equipment but it does require cannulation of the portal vein, the hepatic vein and the superior mesenteric artery.

Electromagnetic flowmeters can only be used to measure total hepatic blood flow when the abdomen has been opened and cannot be applied for preoperative estimation.

In three dogs direct parenchymal injection of xenon-133 gave a significantly lower blood flow than that produced by the other methods. The theoretical slow diffusion effect due to the injection of a bolus of fluid directly into the parenchyma has been avoided by the use of very small volumes of xenon-133 (0·1 ml). In order to avoid any artificially slow clearance due to retained activity in the injection syringe, a fine needle was employed and removed directly after the injection.

It would seem more likely that the results of direct injection of xenon-133 do not correlate well with the other three methods because this indicator is applied at tissue level. The portal injection of xenon-133, the ^{51}Cr-RBCs and the electromagnetic flowmeters are not applied at tissue level, and therefore measure *total* hepatic flow, including any intrahepatic portavenous shunting that may occur. The inclusion of shunted flow will give a value for hepatic blood flow higher than actual tissue perfusion. Since a direct injection of xenon-133 is cleared only by blood perfusing the parenchyma, this method should avoid shunted flow and measure the 'nutritional' liver blood flow, i.e. that which comes in contact with the sinusoids. This theory is supported by the fact that all the values obtained from direct injection of xenon-133 are lower than those measured by other methods, and also by the correlation between the results of direct injections within the group of dogs.

In conclusion, it appears that xenon-133 clearance is the least invasive, simplest and quickest of the three techniques, and as such is the most suitable for clinical studies. It is also accurate, reproducible and measures total liver blood flow. We are at present using this technique prior to creating portasystemic shunts in patients with portal hypertension to assess its value as a predictive test of postoperative liver function.

Exploration of the common bile duct: a comparative study

K. D. VELLACOTT AND P. H. POWELL*

SUMMARY

The results of a retrospective comparative study of 122 patients who underwent explorations of the common bile duct in a district general hospital over a 5-year period are presented. Seventy-eight patients had a supraduodenal choledochotomy, 32 had a transduodenal sphincterotomy and 12 had a combination of both procedures.

Particular attention was paid to postoperative complications in relation to the grade of the surgeon performing the operation and also to the age of the patient.

A total of 78 (64 per cent) patients had definite stones in the common bile duct. Of these patients, 7 (9 per cent) were subsequently shown to have retained stones, all having been operated on by registrars. Registrars also did more negative explorations than consultants.

Nine patients (7·4 per cent) died, all but 1 of them being over the age of 70 and 4 of them having had a combined procedure.

We conclude that transduodenal exploration should be avoided in patients over 70, particularly when added to a supraduodenal exploration.

CHOLECYSTECTOMY is the commonest elective abdominal operation performed in this country and between 10 and 49 per cent of these patients will have their common bile ducts explored (Le Quesne, 1964). The usual method of exploring the common bile duct has been by a supraduodenal approach, opening the duct as it lies in the free border of the lesser omentum with subsequent closure around a T tube, and this remains the method of choice for most British surgeons. This method, however, is not without complications and attention has been drawn from time to time to its disadvantages, the major one being the relatively high incidence of retained stones, which varies between 4 and 22 per cent in different series (Way et al., 1972, Glenn, 1974; Corlette et al., 1978). It is also impossible to see the sphincter, and attempted blind dilatation may lead to a false passage.

A second method of exploration was first described by Kocher in 1895 and it involves a transduodenal approach with a sphincterotomy of the duodenal papilla. Advocates of this method have shown a lower incidence of retained stones, no evidence of papillary stenosis after the procedure and, though there is reflux in many cases, this was not associated with postoperative cholangitis (Peel et al., 1975). Critics of the method have suggested a higher incidence of pancreatitis after sphincterotomy.

A third method involves a combination of both approaches and is usually used where a supraduodenal approach has failed, owing to either a stricture at the lower end of the bile duct or an impacted stone. Recently it has been suggested that this combined approach should be used electively in certain selected patients who have multiple stones, residual stones after previous surgery, stricture at the papilla or impacted stones in the ampullary region (Aubrey and Edwards, 1978). The advantage of using the method electively would be that a protracted attempt at a supraduodenal exploration could be avoided.

This retrospective study was conducted in a district general hospital to compare the results after these three procedures and to relate the results to the grade of the surgeon performing the operation.

Patients and methods

Cheltenham General Hospital is a district hospital serving a population of 200 000. There are three general surgeons, two of whom use the supraduodenal method of exploration while the other uses the transduodenal approach preferentially. Each expected their junior staff to carry out similar procedures. During the 5-year period from 1973 to 1977, 630 cholecystectomies were performed. Of these patients, 126 (20 per cent) underwent explorations of the common bile duct. Four of these patients were lost to follow-up, so that 122 patients are included in the study.

Patients were seen routinely in the outpatients department after their operations and those with persisting symptoms had intravenous cholangiograms. Those patients who were symptom-free, and had been discharged from the outpatients clinic, were not followed up further.

The operations were carried out in a standard manner and all the patients had peroperative cholangiography. There were 90 patients who had supraduodenal explorations, including those who had an additional sphincterotomy, and these were all closed around a T tube. Fifty of the patients had on-table postexploratory T tube cholangiograms and all 90 had T tube cholangiograms on or about the tenth postoperative day. Both types of exploration were drained postoperatively. Choledochoduodenostomy was not performed.

The number of cases in each group and the grade of surgeon performing the operation are shown in *Table I*.

The ages of the patients ranged from 19 to 91 years with a mean age of 66. Women predominated in the ratio of 2 : 1 (female 84, male 38).

Table I: NUMBERS IN EACH GROUP AND GRADE OF SURGEON PERFORMING THE OPERATION

	Supraduodenal	Transduodenal	Combined
Consultant	40	21	6
Registrar	38	11	6
Total	78	32	12

Results

Of the 122 patients explored, 78 (64 per cent) had stones in the common bile duct, giving an incidence of 12 per cent for the whole group of 630 cholecystectomies. Twenty-seven (61 per cent) of the remaining 44 operations where no stones were found were performed by registrars. Reasons for these negative explorations were dilated common bile ducts with a history of previous jaundice (14), no flow into the duodenum (15) and filling defects seen on operative cholangiography (15). Three patients in whom no stones were found in the common bile duct died. One had a transduodenal sphincterotomy for a very dilated common bile duct and the other 2 had a

combined procedure for apparent papillary stenosis. All 3 patients were jaundiced.

In the 504 patients who had a cholecystectomy without exploration of the common bile duct, there were 5 deaths (a mortality of 1 per cent); in the group of 122 patients studied there were 9 deaths (a mortality of 7·4 per cent). If the deaths of patients who had negative explorations are taken separately, then the mortality in the explored group with stones was 6 out of 78 (7·6 per cent) and in those with no stones in the ducts, 3 out of 44 (6·8 per cent).

There were 2 (2·5 per cent) deaths in the supraduodenal group, 3 (9·6 per cent), in the transduodenal group and 4 (33·3 per cent) in the combined group. All except one of these patients was over 70 years of age (*Table II*). Four patients who had advanced obstructive jaundice died of renal failure. The mean ages for each group and the mortality in patients over 70 is shown in *Table III*.

None of the 12 patients in the combined group had this procedure performed as an elective operation. Eleven patients had initial supraduodenal explorations, 4 patients having impacted stones which could not be removed from above, and 7 had tight papillae which would not permit the passage of a small dilator from above and showed no flow into the duodenum on cholangiography. The remaining patient had an attempted transduodenal exploration by a registrar, but the papilla could not be found and a supraduodenal exploration was performed.

There were 6 retained stones in the supraduodenal group (7·7 per cent) and 1 retained stone in the combined group demonstrated by postoperative T tube cholangiography (*Table IV*). No patient in the transduodenal group has developed any symptoms to suggest retained stones. Five of the patients had on-table post-exploratory T tube cholangiography at which the retained stones were not detected. Retrospective examination of these films showed the stones to have been demonstrated in 2 cases. One patient who did not have an on-table T tube cholangiogram had an initial negative exploration. Two patients had their retained stones removed by further surgery. One patient had an endoscopic sphincterotomy but developed a duodenal perforation and died after further surgery. The remaining 4 patients have developed no symptoms from their retained stones and are being kept under regular review as outpatients. If the negative explorations are excluded, the incidence of retained stones in this study is 7 out of 78 operations (9 per cent).

Wound infection was defined as the presence of pus and there was an overall incidence of 18·2 per cent. There was no significant difference between the transduodenal and supraduodenal groups, as shown in *Table V*. Prophylactic antibiotics were not used routinely.

The incidence of wound infection was less in the combined group but 3 of the patients in the group died within 1 week.

There was also no significant difference in the length of hospital stay between the supraduodenal and transduodenal group, but this was considerably longer in the combined group (*Table VI*).

Discussion

The exploration rate in this study was exactly 20 per cent and there was a very high mortality and morbidity in those patients who underwent a combined supraduodenal and transduodenal exploration. All of these patients except one initially had a supraduodenal exploration and was therefore subjected to protracted operations. It was in this group that the only 2 cases of pancreatitis occurred and the amount of instrumentation was probably responsible for this, though both patients had T tubes. Keighley and Graham (1973) found a high incidence of pancreatitis after explorations of the common bile duct, particularly in those who had had a combined supraduodenal and transduodenal approach. Pancreatitis occurred in all 4 cases quoted by them. A much lower incidence of clinical pancreatitis has been found by other authors (Peel et al., 1975; Aubrey and Edwards, 1978),

PULSE VOLUME RECORDER (PVR®)*

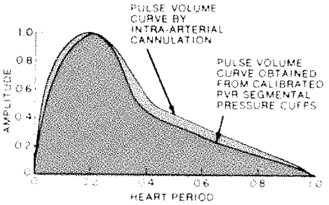
The NON-INVASIVE Clinical Vascular Laboratory

An Extensively Documented Clinical Procedure for the Quantitative Evaluation of Peripheral Vascular Disease:

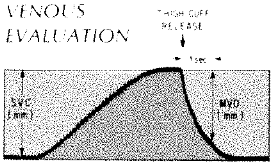
Arterial — Venous — Cerebral

Excellent Long-term Reproducibility and Calibrated Accuracy by Quantitative Segmental Cuff Technique

Ophthalmic artery pressure is read directly on the OPG Attachment of the PVR for the evaluation of collateral circulation to each eye, and its respective cerebral hemisphere.



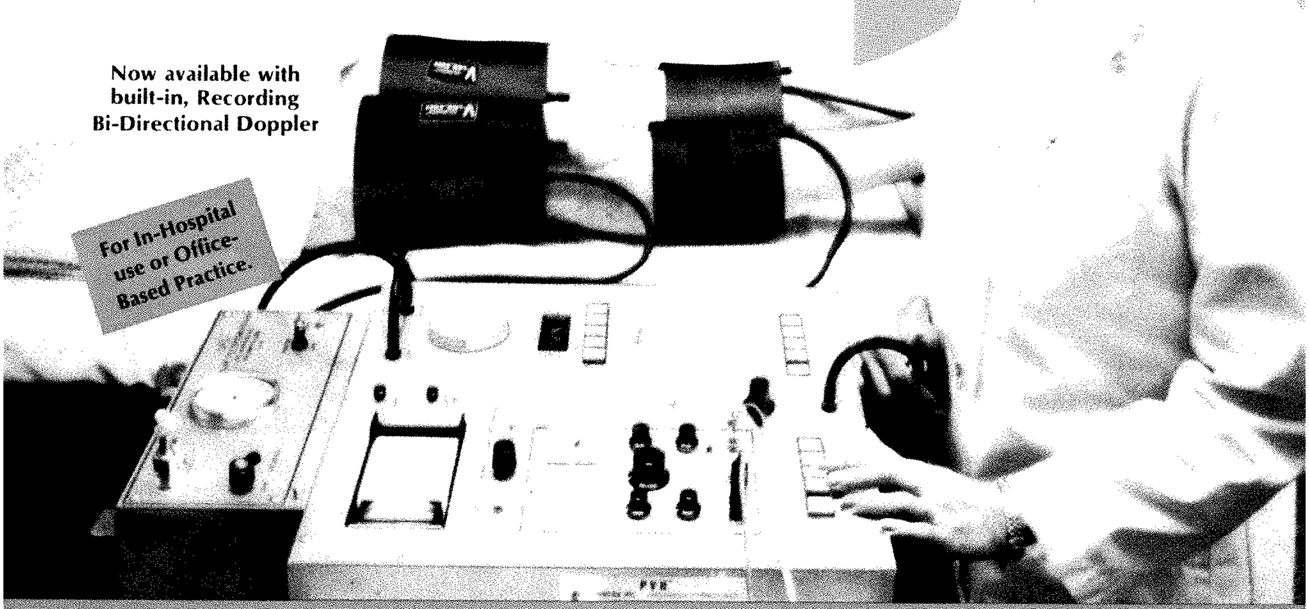
Comparison of pressure contours obtained with the PVR and direct cannulation of the common femoral artery.



A 15-point scale provides approximately 5% false (+) and 2% false (-).

Total Segmental Perfusion (primary vessel plus collaterals) is accurately documented at the thigh-calf-ankle-metatarsal level and digits. The built-in Doppler facilitates the measurement of pressures along the arterial tree.

The COMBINED information of segmental PVR recordings and systolic pressure gradient establishes a clinically accurate picture of functional perfusion.



Now available with built-in, Recording Bi-Directional Doppler

For In-Hospital use or Office-Based Practice.

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*
*not available in the Republic of Ireland

though the serum amylase may be raised without symptoms. This study showed no cases of clinical pancreatitis in either the supraduodenal or transduodenal group.

The grade of the surgeon performing the operation did not affect the mortality or morbidity in any group except in the case of retained stones, registrars having performed all of these operations. This would suggest that experience does play an important part in preventing this major complication of explorations of the common bile duct. Most general surgeons are unlikely to explore more than 12 common bile ducts in a year, so that it will take several years to become fully experienced in the technique. Most retained stones can be detected on postexploratory T tube cholangiography at the time of operation. The fact that 5 of the 7 cases with retained stones in this study had had postexploratory T tube cholangiograms illustrates that cholangiography is not infallible and is often extremely difficult to interpret. Corlette et al. (1978) showed an alarmingly high incidence of retained stones of 22 per cent. On retrospective examination of the postexploratory T tube cholangiograms, Corlette and colleagues found that in 16 of the 22 cases the stones were shown by the radiographs at the time of operation, but were overlooked. However, the examination may not always reveal retained stones and ducts can be explored in the presence of a normal cholangiogram and stones found (Way et al., 1972).

We were unable to demonstrate any significant complications attributable directly to T tube drainage. Ascending cholangitis occurred in 1 patient in the supraduodenal and 1 in the transduodenal group. However, there were 2 cases of septicaemia in the supraduodenal group (*Table IV*). Chande and Devitt (1973) suggested primary closure of the choledochotomy as they had shown a higher morbidity in patients with T tubes. With increasing success in dissolving stones with solutions infused down T tubes (Gardner et al., 1975; Chary, 1977) or by removal with a modified Dormia basket (Christiansen et al., 1978), we feel that T tube drainage should still be used after supraduodenal explorations. Endoscopists are also obtaining good results in the treatment of stones in the common bile duct by endoscopic sphincterotomy and basket extraction. The mortality rate for the procedure can be as low as 1·4 per cent (Safrany, 1978).

The mortality for patients over 70 years of age in the transduodenal and combined groups was very high. Johnson and Rains (1972) showed that in a series of 50 patients who had had a choledochoduodenostomy performed, 25 of whom were over 70, there were no postoperative deaths. Where exploration of the common bile duct by the supraduodenal method is proving difficult, and the operation likely to become prolonged, it would seem that a lower mortality could be obtained by doing a choledochoduodenostomy preferentially rather than risking a transduodenal sphincterotomy. Our findings would suggest that any transduodenal exploration should be avoided over the age of 70.

There was a surprisingly low incidence of thromboembolism, 1 case of deep vein thrombosis and 1 pulmonary embolus, though a proportion of the patients did receive low dose heparin treatment. In contrast, Keighley et al. (1976) showed a 12 per cent incidence of thromboembolism in patients with T tube drainage.

Acknowledgements

We would like to thank Mr P. Boreham, Mr S. Haynes and Mr J. Fairgrieve, consultant surgeons, for permission to study the case records of their patients. We would also like to thank Mr C. B. Williams for his help in the preparation of this paper.

Renal function and other factors in obstructive jaundice

M. E. M. ALLISON, C. R. M. PRENTICE, A. C. KENNEDY AND L. H. BLUMGART*

SUMMARY

Renal function and other factors that possibly affect the outcome of operation were measured in 24 patients with obstructive jaundice and in 15 non-jaundiced controls. The preoperative features that were associated with a poor postoperative recovery from obstructive jaundice were a raised serum fibrinogen/fibrin degradation product concentration, infection, hypoalbuminaemia and a low glomerular filtration rate. Preoperative serum fibrinogen/fibrin degradation product concentrations were raised in 4 of the 6 jaundiced patients who died after surgery but in none of the controls, in whom there was no mortality.

In the jaundiced patients there was a greater incidence of postoperative renal impairment than in the controls. All patients were given mannitol during operation. Further mannitol was required after surgery in 13 of the 24 jaundiced patients in order to maintain urine flow rate despite adequate intravenous fluids being given. In contrast, only 1 of the 15 control patients required post-operative mannitol.

It is emphasized that repeated doses of mannitol can lead to a profound natriuresis and adequate intravenous saline should be given.

ACUTE renal failure after biliary tract surgery was first described in detail by two German surgeons, Clairmont and von Haberer, in 1911. They reported 5 women who died with acute uraemia shortly after cholecystectomy. Numerous descriptions of renal insufficiency after operations on patients with obstructive jaundice followed (Bartlett, 1933), the reported incidence varying from 6 per cent (Williams et al., 1960) to 12 per cent (Funck-Brentano et al., 1963). Uraemia was the commonest direct cause of death postoperatively in 350 patients with obstructive jaundice studied from 1947 to 1959 by Williams et al. (1960).

These findings led Dawson (1964) to suggest that the presence of obstructive jaundice might 'render the kidney more sensitive to decreased blood flow—that is, anoxia'. His observations on the structure and function of the rat kidney after temporary clamping of the renal artery showed that the incidence of both acute tubular necrosis and acute renal failure was higher in animals with obstructive jaundice. Intraperitoneal mannitol greatly reduced the effect (Dawson, 1964; Dawson and Stirling, 1964). Later studies on 7 patients with obstructive jaundice (Dawson, 1965) showed that a mannitol diuresis begun just before surgery and maintained for 2–3 days thereafter was associated with a less marked fall in creatinine clearance postoperatively.

The cause of the increased sensitivity of the kidney of a patient or experimental animal with jaundice remains uncertain; suggestions have included relative hypovolaemia (Williams et al., 1960; Cattell and Birnstingl, 1964), conjugated bilirubin (Baum et al., 1969), bile salts (Stewart and Cantarow, 1935; Aoyagi and Lowenstein, 1968), excessive quantities of vasodilator substance (Frank et al., 1946; Shorr et al., 1948), diminished renal cortical blood flow (Bloom et al., 1974) and increased sensitivity to the α-adrenergic effects of noradrenaline in obstructive jaundice (Bloom et al., 1975). Most recently the importance of renovascular fibrin deposition, perhaps related to a delayed clearance of endotoxin by the damaged liver, has been stressed (Wardle and Wright, 1970; Wilkinson et al., 1974; Wardle, 1975; Bailey, 1976).

In order to examine the relationship between obstructive jaundice, renal function and intravascular coagulation more closely, we have compared sequential observations in patients with obstructive jaundice to those in non-jaundiced control patients. As a marker for the presence of fibrin the estimation of fibrinogen/fibrin degradation products (FDP) was chosen. Serum FDP in most instances are formed from fibrin rather than fibrinogen substrate and thus reflect the extent of fibrin formation (Gallimore et al., 1972). Urinary FDP reflect mainly the formation and proteolysis of fibrin within the renal tract (Clarkson et al., 1971; Ekberg and Pandolfi, 1975).

We found that preoperative features with an adverse effect on postoperative recovery were a raised serum FDP concentration, infection, hypoalbuminaemia and a low glomerular filtration rate (GFR).

Patients and methods

A prospective study was made of 24 patients with obstructive jaundice (14 male, 10 female, mean age 61 years) and 15 non-jaundiced control patients (10 male, 5 female, mean age 49 years). admitted to the general surgical wards or to the University Department of Surgery, Glasgow Royal Infirmary, during 1974–5. Details of diagnosis and operations in both groups are given in *Tables I* and *II*. A malignant condition was present in 58 per cent of the jaundiced patients and 33 per cent of the control subjects.

Preoperatively, 24-h urine collections were carried out by spontaneous voiding and corresponding serum samples were obtained on at least two occasions for measurement of serum and urine creatinine and creatinine clearance (GFR), urinary sodium and potassium excretion rate and serum and urinary FDP levels. All the creatinine clearance levels have been corrected to the value for a body surface area of 1·73 m². Serum and urinary creatinine concentrations were obtained using the method of Hare (1950), electrolytes were measured on a direct-reading flame photometer (Instrumentation Laboratories Watertown, Mass., USA) and serum and urinary FDP concentrations were measured using Wellcome HA14 FDP test kits (Wellcome Laboratories, Beckenham, Kent), which are based on the red cell haemagglutination inhibition technique (Merskey et al., 1966). Urine was concentrated 25 times before assay using the Minicon B15 concentrator (Amicon Corp., Lexington, Mass., USA). The addition of the proteolytic inhibitor aprotinin (Trasylol, Bayer) did not alter serum FDP concentrations in a preliminary study, and therefore was not used. Routine examinations of full blood count, urea and electrolytes, liver function studies and blood pressure were made and urine and sputum cultures were obtained if there was any suggestion of infection. Maximum urinary concentrating ability was determined in 16 of the patients with obstructive jaundice and in 5 of the control subjects by measuring urine osmolality after a 12-h overnight fast and again 4 h after a subcutaneous

injection of pitressin tannate in oil. Differences between jaundiced and control patients have been analysed using Student's *t* test (not significant if $P > 0{\cdot}05$).

Intravenous fluids (a minimum of 500 ml of isotonic saline and 500 ml of 5 per cent dextrose) were given for at least 12 h before operation together with mannitol 20 g intravenously 1 h before operation and a further 20 g during operation. Postoperatively, mannitol was given during the first 3 postoperative days (20 g i.v. over 15 min) to patients whose urine flow rate was less than 40 ml/h on two successive occasions despite adequate intravenous fluid therapy or to those who became hypotensive.

After surgery 24-h urine collections were made for at least 5 consecutive days and all preoperative serum and urine measurements were repeated. Patients with obstructive jaundice and some of the control subjects were catheterized for 2–3 days. Antibiotics were given only to control clinically significant infection. Bile cultures were obtained during operation in 12 of the 24 patients with obstructive jaundice.

Results

Before operation

Significant differences were found between the jaundiced and non-jaundiced groups of patients (*Table III*). Mean serum albumin concentration, mean haematocrit and mean urinary concentrating ability were significantly reduced in patients with obstructive jaundice. Serum FDP concentrations were raised (>10 μg/ml) in 9 of the 16 jaundiced patients in whom this was measured, but in none of the 13 control subjects (*Fig*. 1). This difference was not related to the incidence of preoperative infection, as judged by sputum culture, urine culture or bile culture, nor to the incidence of malignancy.

Fibrin degradation products were present in the urine of 6 of the 24 patients with obstructive jaundice compared with 1 of 14 control patients. In none did the excretion rate exceed 700 μg/d except in 1 jaundiced subject with a urinary tract infection (3·8 mg/d).

Mean GFR, sodium and potassium excretion rates did not differ significantly between the two groups—jaundice : control, GFR 81·2 ± 30·2 s.d. : 91·2 ± 22·7 s.d. ml min^{-1} 1·73 m^{-2}; sodium excretion, 101 ± 58 s.d. : 127 ± 52 s.d. mmol/24 h; potassium excretion, 34 ± 13 s.d. : 39 ± 13 s.d. mmol/24 h. However, there was a large variation in GFR in patients with obstructive jaundice (*Fig*. 2), not related to serum bilirubin concentration and in 5 jaundiced patients preoperative GFR was lower than in any of the control subjects and in 1 of these serum creatinine concentration was significantly raised. None gave a history of previous renal disease.

After surgery

Renal function: Acute renal failure, defined as an increase in serum creatinine concentration above the normal range, oliguria and a fall in GFR, was found within 2 weeks of operation in 4 patients with obstructive jaundice (*Fig*. 2), 3 of whom had had a low preoperative GFR and 1 of whom had had established renal insufficiency before surgery. None of the control patients had postoperative renal failure.

The percentage changes in urine flow rate, GFR and urinary sodium excretion during the first postoperative day as compared with the preoperative baseline levels are shown in *Table IV*. The variation in individual values for sodium excretion is plotted in *Fig*. 3 for the first 3 days. All patients had received mannitol before and during operation. Thirteen of the jaundiced patients required further mannitol postoperatively (jaundice group B in *Table IV* and *Fig*. 3) because of oliguria despite intravenous fluids. Only 1 of the control subjects required mannitol and this patient has not been included in the analysis (*Fig*. 3).

Table I: DIAGNOSIS AND OPERATION IN 24 PATIENTS WITH OBSTRUCTIVE JAUNDICE

No.	Diagnosis	Operation
9	Ca pancreas	Cholecystoenterostomy (5) Pancreaticoduodenectomy (2) Choledochoduodenostomy (1) Laparotomy (1)
3	Ca common bile duct	Laparotomy (1) Cholecystoenterostomy (2)
1	Ca common hepatic duct	Hepaticodochocholecystostomy
1	Ca gallbladder	Cholecystectomy
5	Cholelithiasis	Cholecystectomy and exploration of CBD (3) Choledochojejunostomy (2)
3	Stricture	Hepaticojejunostomy (1) Choledochojejunostomy (1) Hepaticoduodenostomy with U tube (1)
1	Mucocoele of gallbladder with external compression of CBD	Cholecystectomy
1	Cholangitis	Laparotomy

Figures in parentheses refer to number of patients.
Ca, Carcinoma; CBD, common bile duct.

Table II: DIAGNOSIS AND OPERATION IN 15 NON-JAUNDICED CONTROL PATIENTS

No.	Diagnosis	Operation
7	Duodenal ulcer	Partial gastrectomy, vagotomy (3) Gastroenterostomy, vagotomy (3) Pyloroplasty, vagotomy (1)
3	Ca pancreas	Pancreaticoduodenectomy (3)
2	Cholelithiasis	Cholecystectomy (2)
1	Ca stomach	Partial gastrectomy
1	Ca colon	Sigmoid resection
1	Chronic pancreatitis, post-cholecystectomy stricture	Pancreaticoduodenectomy

Figures in parentheses refer to number of patients.
Ca, carcinoma.

Table III: PREOPERATIVE FEATURES (mean ± s.d.)

	Haematocrit (%)	Serum albumin (g/l)	Serum FDP (>10 μg/ml)
Jaundice	36·1 (22) ±4·6	32·1 (22) ±6·3	9 (16)
P	<0·001	<0·02	—
Control	42·7 (14) ±4 1	38·0 (10) ±4·1	0 (13)

Figures in parentheses refer to number of patients.

Table IV: MEAN PERCENTAGE CHANGE IN URINE FLOW RATE, GFR AND URINARY SODIUM EXCRETION DURING FIRST POSTOPERATIVE DAY

	Control	Jaundiced A	Jaundiced B
Urine flow rate	↑ 88·7	↑ 16·5	↑ 20
GFR	↓ 1·2	↓ 3·3	↑ 16 9
Sodium excretion	↓ 12·4	↓ 7·9	↓ 11·2

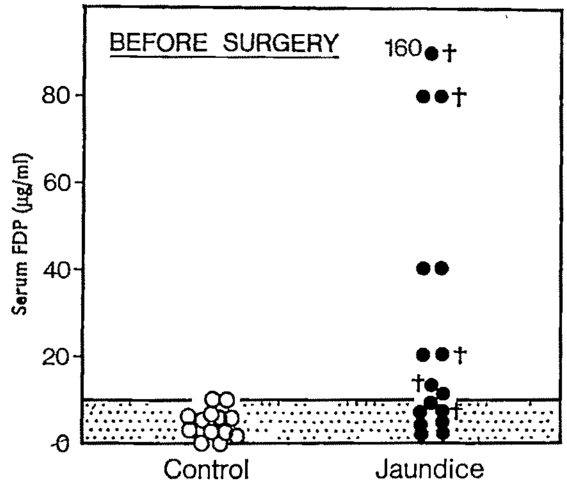

Fig. 1. Serum fibrinogen degradation product (FDP) concentration (µg/ml) before operation in 16 patients with obstructive jaundice and in 13 control patients. Values of less than 10 µg/ml have been accepted as within the normal range for healthy subjects. Patients dying within 2 weeks of operation are marked †.

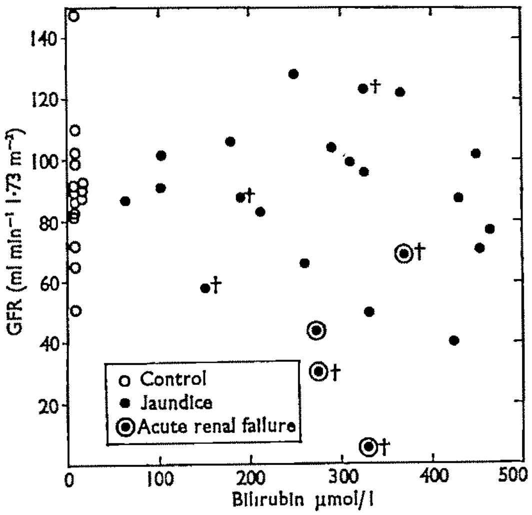

Fig. 2. Relationship of GFR (ml min^{-1} 1·73 m^{-2}) and serum bilirubin concentration (µmol/l) before operation to incidence of acute renal failure and/or death (†) within the first 2 postoperative weeks.

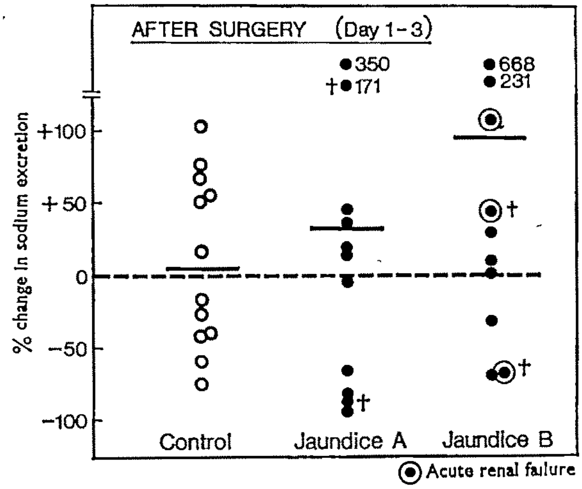

Fig. 3. Percentage change in sodium excretion during the first 3 postoperative days in 12 control subjects and 21 patients with obstructive jaundice. Control subjects and jaundice group A received mannitol only before and during surgery, while jaundice group B received further mannitiol over the first 2 postoperative days. The mean value for each group is represented by the horizontal line.

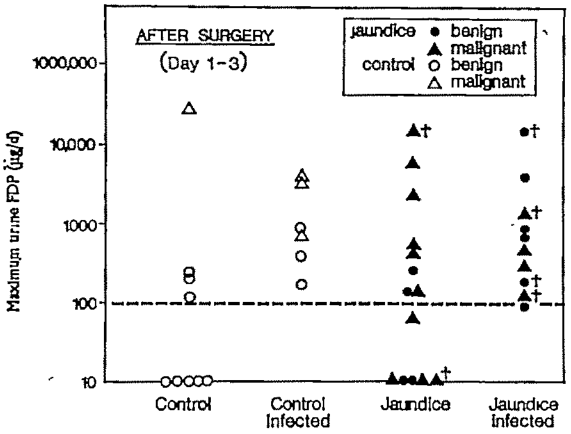

Fig. 4. Maximum urine FDP excretion rate (µg/d, logarithmic scale) during the first 3 postoperative days in control and jaundice patients with benign or malignant disease and with or without infection. The † indicates death within 2 weeks of operation. The broken line indicates the approximate upper limit of normal (100 µg/d).

The changes in urine flow rate and GFR were similar in all three groups; there was a diuresis but little alteration in mean GFR. In 18 out of the 24 patients with obstructive jaundice (75 per cent) GFR fell at least once within the first 3 postoperative days. GFR fell in 7 out of 14 control patients (50 per cent). In obstructive jaundice the mean maximum percentage fall in GFR was 35·7 ± 18·7 per cent ($n = 18$) and in the control group it was 52·5 ± 16·4 per cent ($n = 7$).

Sodium excretion fell during the first postoperative day in all patients despite the use of mannitol and intravenous fluids (*Table IV*). A natriuresis occurred during the next 2 days, however, in the patients with obstructive jaundice, especially in those given postoperative mannitol (*Fig.* 3, jaundice B).

Bile was taken for culture during operation in 12 patients with obstructive jaundice. A positive result was found in 3 patients, all of whom had gallstones and/or stricture of the common bile duct.

Deaths: Six of the 24 patients with obstructive jaundice died within 2 weeks of operation but none of the control patients; in 4 patients death was due to overwhelming infection, in 1 to uraemia and infection, while the final patient succumbed to a pancreatic carcinoma following laparotomy. Serum FDP concentrations before operation were measured in 4 of the 6 who died and were more than 10 µg/ml in all of them; in contrast, none of the control patients had elevated preoperative serum FDP levels. Forty per cent of the surviving jaundiced group also had raised preoperative serum FDP concentrations (*Fig.* 1).

FDP levels: Serum and urinary FDP levels rose after surgery in both jaundiced and control patients. Serum FDP concentrations increased significantly over the preoperative value in approximately 25 per cent in both groups (4 out of 14 jaundiced patients, 3 out of 12 control patients). These increases were associated with severe infection (5 patients) or postoperative haemorrhage (2 patients). A fall in GFR occurred in all of the jaundiced patients and in 1 of the controls, in whom a postoperative rise in serum FDP was seen.

Urinary FDP levels rose in 15 out of the 24 jaundiced subjects after operation and in 10 of 15 control subjects. A marked increase in the urinary FDP excretion rate was associated with severe infection such as bacteraemia or cholangitis in both groups (*Fig.* 4). There was no correlation between the presence of FDP in the blood and urine, very high levels of urinary FDP appearing in the urine at times when the serum FDP concentrations were not raised and vice versa. There was also no correlation between the urinary FDP excretion rate and change in GFR postoperatively. In 1 patient, however, a 22-year-old girl having undergone removal of a large mucocoele of the gallbladder, an episode of acute blood loss was associated with a sharp fall in GFR and a concomitant rise in urinary FDP excretion, which fell again as GFR rose 24 h later.

Discussion

It is widely accepted that there is an increased incidence of renal impairment in jaundiced patients, particularly after surgery or shock. Patients with resultant 'hepatorenal failure' seldom recover (Conn, 1973). We, therefore, set out to study the reasons why patients with obstructive jaundice might be particularly at risk of developing acute renal failure and what might be done to help them.

This report emphasizes two features of the problem. First, the preoperative features that were associated with a poor postoperative recovery from obstructive jaundice: these appear to be infection, hypoalbuminaemia, a low GFR and, most interestingly, a raised serum FDP concentration. This last factor was above control values in all 4 of the patients who died and in whom it had been measured.

Second, renal function can be well maintained postoperatively in patients with obstructive jaundice provided that adequate intravenous fluids and mannitol are given. The use of mannitol in obstructive jaundice, however, is associated with a marked natriuresis on days 2–3 postoperatively.

The association between raised preoperative FDP levels and a poor postoperative prognosis may help in the prediction of high risk patients, although the underlying mechanisms causing the FDP rise are not clear. It is known that ill patients with systemic complications have raised serum FDP levels (Wood et al., 1972) and that some of these FDP may be derived from fibrin within thrombi or pulmonary emboli (Ruckley et al., 1970). Alternatively, the FDP may be the end-product of a low-grade process of intravascular coagulation, triggered by stimuli such as bacteraemia or endotoxaemia (Merskey et al., 1967; Colman et al., 1972; Levin, 1973; Müller-Berghaus et al., 1976).

It is known that hepatic disease favours intravascular coagulation due to impaired clearance of activated coagulation enzymes and plasminogen activation (Deykin, 1966). In this situation, the jaundiced patients would be at greater risk than the non-jaundiced ones. A further source of FDP might be fibrinogen or fibrin laid down around areas of inflammation at extravascular sites and reabsorbed after digestion by the lymphatic system. The mechanism of so-called 'disseminated extravascular coagulation' has been suggested by several investigators (Straub, 1977), by which FDP, derived from extravascular fibrinogen or fibrin, are reabsorbed into the circulation via the lymphatic system.

The urine FDP levels did not correlate well with serum FDP, in keeping with observations that most urine FDP are derived locally from the kidney rather than reflecting filtered serum FDP (Clarkson et al., 1971; Ekberg and Pandolfi, 1975). The fact that jaundiced patients had significantly higher preoperative FDP levels in both serum and urine may again reflect the increased tendency to fibrin formation in jaundice. In view of the findings of Clarkson et al. (1971) that no significant increase in urinary tract FDP excretion occurred as a result of renal tract infection, it is unlikely that this was the cause of the rise in urine FDP in patients with obstructive jaundice. It must be remembered that patients labelled 'infected' in *Fig.* 4 had evidence of either systemic or urinary infections; only 3 of the 16 had urinary infections, detected by urine culture, at the time of urine FDP estimation, the other patients having bacteraemia or cholangitis. Thus, there is a suggestion, as seen in *Fig.* 4, that systemic infection is associated with increased urine FDP excretion, in that only non-infected patients had normal urine FDP levels. Whether the infective process is the direct cause of renal fibrin deposition and urine FDP production is uncertain.

The possibility that intravascular coagulation in jaundice might precipitate renal failure by means of glomerular fibrin deposition has been explored (Wardle and Wright, 1970; Wilkinson et al., 1974; Wardle, 1975; Bailey, 1976). Using the Limulus assay (Reinhold and Fine, 1971), Wardle (1975) detected postoperative endotoxaemia in 73 per cent of patients with obstructive jaundice. Similarly, Bailey (1976) found peripheral endotoxaemia in just over half of his jaundiced patients postoperatively. We did not measure blood endotoxin levels in this study and the significance of our observation remains speculative.

With regard to the postoperative progress of our patients with obstructive jaundice, 4 had evidence of significant renal impairment while this was present in none of the control subjects, although the distribution of malignant disease and infection was roughly comparable in both. All received a similar volume of intravenous saline and dextrose and a similar quantity of intravenous mannitol before and during surgery. While the pattern of changes in urine flow rate, glomerular filtration rate and sodium excretion was roughly comparable in both the control and the jaundiced subjects, two points should be made. First, nearly half of the jaundiced patients required further mannitol postoperatively in order to maintain their urine flow rate, despite apparently adequate intravenous fluids. Secondly, patients given large loads of mannitol had a profound natriuresis during the second and third postoperative days. It is, therefore, important that such patients are given adequate saline postoperatively.

Mannitol is a powerful osmotic diuretic, inhibiting the reabsorption of water and sodium in the proximal tubule and the loop of Henle, thus promoting both a diuresis and a natriuresis in association with volume expansion. There is an increase in total renal blood flow and in medullary blood flow even at very low perfusion pressures (Wendling et al., 1969; Gennari and Kassirer, 1974). Of greater importance, perhaps, is the fact that mannitol appears to have the ability to prevent endothelial cell swelling during hypoperfusion, thus stopping the 'no reflow phenomenon' (Flores et al., 1972). These properties have led to the widespread use of mannitol as a prophylactic agent during potential renal ischaemia and as a substance capable of reversing incipient acute renal failure (Barry et al., 1961; Eliahou, 1964; Luke et al., 1970; Morris et al., 1972). Our patients received a relatively small quantity of mannitol compared with that suggested by Dawson in 1965. Despite this, renal function was well maintained postoperatively in most patients.

Our observations emphasize the importance of prompt diagnosis and relief of bile duct obstruction. Preoperative investigative techniques such as ultrasound, percutaneous transhepatic cholangiography and endoscopic retrograde cholangiopancreatography now allow correct diagnosis in almost all patients (Blumgart, 1978). In many patients a period of biliary drainage will permit recovery of liver function with improvement in nutrition, coagulation disorders and renal function and possibly increased resistance to endotoxaemia (Blumgart, 1978) before proceeding to major resectional surgery. Even bypass operations, however, are associated with an appreciable mortality of approximately 20 per cent (Nakase et al., 1977). Careful preoperative assessment of nutritional and coagulation status, as well as of renal function, is required.

Acknowledgements

We wish to thank Mrs Andrea Duncan, Mrs Christine Pidgeon and Miss Mary Fraser, BSc, for carrying out the serum and urine FDP measurements and Miss Pamela Stevenson for measurement of urine and serum creatinine concentration. We also thank the nursing staff of Wards 32 and 33, Glasgow Royal Infirmary, for forbearance in carrying out urine collections.

Acute pancreatitis in Hong Kong

G. B. ONG, K. H. LAM, S. K. LAM, T. K. LIM AND JOHN WONG*

SUMMARY

A series of 311 Chinese patients with acute pancreatitis admitted to Queen Mary Hospital, Hong Kong, over a 10-year period is reviewed. Biliary tract disease was associated with pancreatitis in 52·4 per cent of patients and 77·9 per cent of them had stones, mud or parasites in the common bile duct. Fever and jaundice were present in 55 per cent and 41·2 per cent of patients respectively. Because of the prevalence of recurrent pyogenic cholangitis among the indigenous population, emergency operation, with the aim of common duct decompression, was conducted in 54·3 per cent of patients during the acute episode, with a mortality rate of 14·8 per cent. Five of 142 patients (3·5 per cent) died whilst on conservative treatment and all 5 had haemorrhagic pancreatitis. The overall mortality rate was 9·6 per cent. Exploration of the common bile duct, which was carried out in 57·4 per cent of patients in the acute phase, was not associated with a higher mortality than when laparotomy alone was performed, and 19 patients had sphincteroplasty without any death. Subtotal pancreatectomy was performed in 2 patients with haemorrhagic pancreatitis with 1 death.

MORTALITY rates of acute pancreatitis reported from different countries vary quite widely. These variations have been attributed to associated aetiological factors in different proportions as well as to different racial compositions (Albo et al., 1963; Marks and Banks, 1963; Mayday and Pheils, 1970; Imrie, 1974; Olsen, 1974). However, even in the same country, mortality rates have varied depending on whether the study was carried out prospectively or retrospectively (Trapnell and Anderson, 1967; Imrie, 1974; Trapnell et al., 1974; Imrie and Whyte, 1975). Furthermore, the mortality rate associated with operations in the acute phase has been claimed to be prohibitively high (Imrie, 1974), or not different from that associated with conservative treatment (Trapnell and Anderson, 1967; Trapnell, 1974).

In Hong Kong, where biliary tract disease is common among the indigenous Chinese population, it has been our practice to perform an early operation on patients with acute pancreatitis.

We present here the results of a retrospective study of 311 cases of acute pancreatitis with particular reference to the associated aetiological factors and the results of early surgical intervention.

Patients and methods

Patients

Over a 10-year period from 1967 to 1976 311 patients with acute pancreatitis were admitted to the University Surgical Unit, Queen Mary Hospital, Hong Kong. There were 123 males and 188 females. Age incidence is shown in *Fig.* 1 and the range was 7–86 years with a mean of 47·6 years.

Diagnostic criteria: Patients who presented with a clinical history consistent with acute pancreatitis and confirmed by the finding of a serum amylase of 1000 Somogyi units or more, or urinary diastase of 60 Wohlgemuth units or more were included in this study. Patients with operative or post-mortem findings of acute pancreatitis were also included.

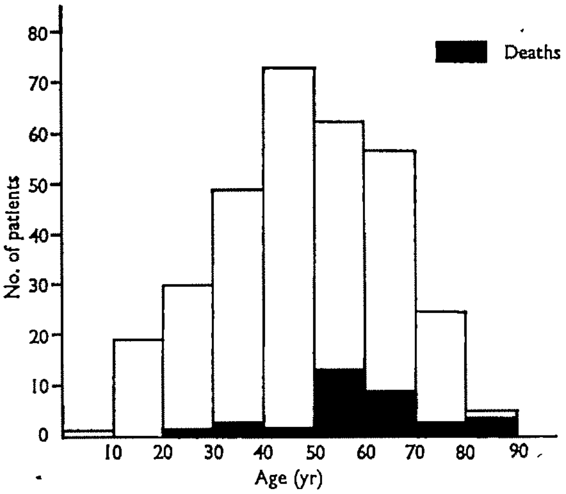

Fig. 1. Age and mortality of cases of acute pancreatitis.

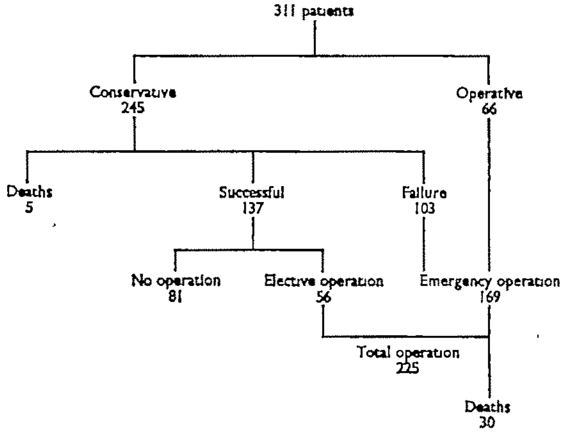

Fig. 2. Summary of treatment and results.

Biliary disease was accepted as an associated factor when confirmation was obtained at operation or at post-mortem examination, or when radiological investigations at least 6 weeks after an acute episode demonstrated stones in the biliary system. All patients successfully treated without operation were investigated radiologically for biliary tract disease with oral cholecystography and intravenous cholangiography.

Patients who drank more than 300 ml of spirits daily for more than 10 years and who suffered from an attack within 36 h of the last bout of drinking were regarded as suffering from alcoholic pancreatitis.

Shock was diagnosed when the blood pressure dropped to 80 mmHg or below at any stage of the acute attack before or after the institution of conservative therapy.

Respiratory failure was diagnosed in any patient who had tachypnoea in spite of oxygen therapy and who showed radiological evidence of diffuse infiltration in both lung fields; or

Correspondence to John Wong.

when arterial oxygen estimations showed a level of 70 mmHg or less.

Renal failure was present when a rise in blood urea of over 20 SI units failed to respond to adequate fluid replacement.

Ileus was present when nasogastric aspiration yielded 500 ml or more per day for 5 days or more and when there was no clinical or radiological evidence of mechanical obstruction.

Haemorrhagic pancreatitis was diagnosed only at operation or post-mortem examination when there was gross retroperitoneal haemorrhage, usually in association with bloody intraperitoneal fluid and fat necrosis. Microscopic evidence of haemorrhage alone was not included.

Associated aetiological factors: The commonest associated condition was biliary tract disease (*Table I*). This accounted for 163 (52·4 per cent) of our patients and 127 (77·9 per cent) had stones, mud or parasites in the common bile duct. Alcoholism was associated in 15·1 per cent and trauma in 7·4 per cent of patients. In 75 patients (24·1 per cent) no associated factors were evident.

Number of attacks on presentation: This presentation represented a first attack in 73·2 per cent of the patients, a second attack in 12·1 per cent, a third attack in 4·8 per cent and 3·9 per cent presented in their sixth or more attack, the maximum being a fourteenth attack in one patient.

Clinical features: Pain was the universal symptom. Fever and jaundice were present in 55 and 41·2 per cent respectively and 10·6 per cent of patients presented in or developed shock in the course of their acute attack. Peritonitis was present in 29·6 per cent and an abdominal mass was found in 5·1 per cent.

Plain X-ray of abdomen: This investigation was of little value in the diagnosis of acute pancreatitis. Gallstones were seen in 4·2 per cent, a sentinel loop in 2·6 per cent and gas in the biliary tree in 0·6 per cent.

Treatment

Management of acute attack: Initial management included nasogastric aspiration, intravenous fluid replacement, analgesics (usually pethidine) and antibiotics (usually ampicillin). Atropine and Trasylol were given to 22 and 9 patients respectively in the past, but these two drugs were not used in recent years.

Patients in shock were monitored by measurement of central venous pressure, hourly urinary output and regular estimations of arterial gases. Plasma infusion and, occasionally, blood were given until blood pressure and urinary output were satisfactory.

Patients who were jaundiced, in shock, or had signs of peritonitis or in whom other diagnoses (particularly recurrent pyogenic cholangitis) were suspected were operated on after initial resuscitative treatment. Since recurrent pyogenic cholangitis may be associated with shock from septicaemia, or peritonitis without clinical jaundice, patients in shock or who had peritonitis during their acute attack were invariably explored, even though the diagnosis of acute pancreatitis was established biochemically. Thus the suspicion of cholangitis either as the primary or an additional diagnosis was the indication for the vast majority of emergency operations. Conservative treatment was deemed to have failed in patients who continued to have severe symptoms or became shocked, or developed signs of peritonitis or jaundice. These patients were also subjected to emergency operations.

Emergency operations were performed on 66 patients (21·2 per cent) soon after admission (*Fig.* 2). Conservative treatment on the remaining 245 patients was successful in 137 (55·9 per cent). One hundred and three patients (42 per cent) failed to respond to conservative treatment and underwent emergency operations up to 10 days after admission. In all, 169 patients (54·3 per cent) were operated on during the course of their acute attack. The indications for operation are shown in *Table II*.

Of the 137 patients successfully managed conservatively, elective operations were performed in 56 (40·9 per cent) because of radiologically demonstrated biliary tract disease (51 patients), or because of development of pancreatic pseudocyst (5 patients). Five patients who had biliary tract disease initially refused operation but because of recurrent attacks subsequently underwent surgery. Eighty-one patients (59·1 per cent) were not operated on. Thus, in total, 225 patients (72·3 per cent) underwent operative treatment either as an emergency or elective procedure.

At operation during the acute attack the pancreas was found to be oedematous in 115 patients (68 per cent), there was haemorrhage in 25 and in 29 patients the gland showed localized necrosis with abscess formation. In 109 of these 169 patients (64·5 per cent) biliary tract disease was present.

Operations performed during acute attack: The procedures carried out and the mortality associated with each procedure are shown in *Table III*. Laparotomy alone or with biopsy or with drainage of the pancreatic bed was performed in 32·5 per cent of patients. Biliary tract operations were performed in all the remainder except 7. The commonest biliary operation was exploration of the common bile duct (57·4 per cent) with or

RPC, Recurrent pyogenic cholangitis.

without an added procedure. Sphincteroplasty was carried out in 19 patients (11·2 per cent). Four patients had pancreatectomies and their clinical summaries are shown in *Table IV*.

Results

Complications of the disease and operations

The complications of the disease are shown in *Table V*. Since over half (54·3 per cent) of our patients were operated on during the acute attack, this Table represents complications that were present on admission or which developed in the course of non-operative treatment. Since the non-operated group was selected on the basis of a clinically mild attack, a relatively low incidence of complications may therefore be expected. Non-fatal postoperative complications are shown in *Table VI*. Some of these complications may be the result of the disease rather than of the operation, and the incidence of complications of the disease may well have been greater if fewer patients had undergone operation.

Respiratory failure occurred in 19 patients and was a significant factor in the death of 14. Renal failure was present in 13 patients and was a contributory cause of death in 11.

Mortality rates

There were 30 deaths (9·6 per cent) in this series. In the group operated on during the acute attack, the mortality rate was 25 out of 169 (14·8 per cent). In the non-operated group, it was 5 out of 142 (3·5 per cent). In the operated group, those who underwent exploration of the common bile duct did not suffer a higher mortality than those who had exploratory laparotomy alone (*Table III*), and 19 patients had sphincteroplasty without a death. Two of 4 patients who had a pancreatectomy died. The causes of death in the operated group are shown in *Table VII*.

The deaths tabulated according to aetiological factors and compared with the overall incidence of each aetiological factor are shown in *Table VIII*. The mean age of the 30 patients who died was 59 years, which was 11·4 years more than the mean age for the whole series. Only 4 deaths occurred in the under-50 age group (2·4 per cent). In the over-50 age group the mortality rate was 26 out of 144 (18·1 per cent).

At operation or post-mortem, the pancreas in the 30 cases who died was seen to be haemorrhagic in 23, showing localized necrosis with abscess in 3 and an oedematous gland in 4. Conversely, when an oedematous pancreas was found at operation the mortality was 4 out of 115 (3·5 per cent), which is the same as in the conservatively treated group. However, when localized necrosis with abscess formation was present

the mortality rose to 3 out of 29 (10·3 per cent), and in those with haemorrhagic pancreatitis the mortality was 72 per cent.

The mortality rates of operative and non-operative management in this series are compared with those in three British series in *Table IX*.

Acute haemorrhagic pancreatitis

Although the exact incidence of this more severe form of pancreatitis in any reported series is unknown (but estimated to be between 10 and 25 per cent; Glazer, 1975), the mortality rate of haemorrhagic pancreatitis, when diagnosed at operation, was very high. In 169 emergency operations during the acute attack, 25 cases of haemorrhagic pancreatitis were found and 18 of them subsequently died (72 per cent). The 5 deaths in the conservatively treated group were all found to have haemorrhagic pancreatitis at post-mortem. Subtotal pancreatectomy was performed in 2 patients with 1 death.

Late results

Of the 311 patients in this series, 107 were not available for follow-up study (30 died in the acute episode, 9 died from other causes after discharge from hospital and 68 defaulted follow-up). Of the remaining 204 patients, 199 (92·6 per cent) were symptom-free and 15 (7·4 per cent) had further attacks. Six of these 15 had biliary tract diseases demonstrated but refused surgery. Five subsequently were operated on and were free of further symptoms. Two patients had attacks after biliary tract surgery but have now been without symptoms for 3 and 8 years respectively. Seven patients had no biliary tract diseases but suffered recurrent attacks; 4 of these 7 patients had biliary surgery without arrest of subsequent attacks.

Discussion

Associated aetiological factors

The incidences of associated aetiological factors in our series are almost identical to those reported in recent British series (Imrie, 1974; Trapnell, 1974), but contrast significantly with American, Australian and South African series (Marks and Banks, 1963; Barraclough and Coupland, 1972; Olsen, 1974) where alcohol was demonstrated to be the cause in half or more of the patients with acute pancreatitis. Biliary tract disease was shown to be the most commonly associated condition in our series (52·4 per cent), although this proved not to be as high as we had previously suspected. Our incidence of unknown causes is high, and is a feature of a retrospective study (Imrie, 1974) as compared with a prospective one (Imrie and Whyte, 1975). Quite likely, more patients in the idiopathic group would be classified as alcoholics if a more searching history was obtained, and the incidence of biliary tract disease would be higher if more refined investigations were performed on patients who recovered from conservative treatment. Only one patient with alcoholic pancreatitis had gallstones, a rare association, also shown by Barraclough and Coupland (1972) though denied by Mayday and Pheils (1970) and Olsen (1974).

In our series, the incidence of ductal stones in patients with biliary tract disease was 77·9 per cent, which was much higher than that reported by Barraclough and Coupland (1972) (11·1 per cent) and by Imrie (1974) (20 per cent). This is reflected in the presentation of a large number of our patients with fever and jaundice from cholangitis. This high incidence of ductal stones encouraged us to operate early in patients with suspected biliary tract disease. Since ductal stones may pass through the ampulla (Acosta and Ledesma, 1974), and in some cases possibly after initiating an attack of pancreatitis, the incidence of ductal stones in reported series is probably underestimated. Furthermore, as radiological diagnosis of biliary tract disease may have false negative results, the true incidence of biliary tract disease may be even higher.

Mortality rate

Mortality rates reported in British series with similar incidences of aetiological factors have been higher than ours: Trapnell and Anderson (1967), 23·4 per cent; Imrie (1974), 18·9 per cent; present series, 9·8 per cent. However, a recent prospective study by Imrie and Whyte (1975) showed that there is a decline in mortality rates (to 11·5 per cent), and the reasons for this have been attributed by the authors to a lower incidence of diagnosis by laparotomy than in the retrospective studies, earlier diagnosis because of clinical awareness, improved methods of serum and urine amylase estimations, an appreciation of the risk from operations and improved care from personal interest in the condition. Since these factors are not features of our retrospective study, it must be concluded that our low mortality rate reflected a different natural history of the disease in our Chinese patients. Similar low mortality rates have been reported by Albo et al. (1963) (11 per cent), Louw et al. (1967) (12 per cent) and Olsen (1974) (6 per cent), where the incidence of alcoholic pancreatitis was high.

Mortality associated with operation in the acute phase of pancreatitis varies greatly in different reports. Those in favour of early operation (Trapnell, 1966; Louw et al., 1967; Kune, 1968; Diaco et al., 1969; Barraclough and Coupland, 1972) claimed that there was no added risk when laparotomy and simple remedial surgery were carried out. On the other hand, Imrie (1974) and Imrie and Whyte (1975), in both retrospective and prospective studies, have shown the mortality rate of operation to be 3½ and 7½ times respectively that of conservative treatment. Our series also demonstrated a greater than fourfold increase in mortality rate associated with operation.

This high mortality is related to the many patients in our series who were operated on in shock and with cholangitis, which gave rise to deaths from infections and respiratory and renal failure.

The high mortality rate associated with acute haemorrhagic pancreatitis is reflected in our series. Since the true incidence of haemorrhagic pancreatitis in any series of acute pancreatitis is not known, reported mortality rates of between 40 per cent and 82 per cent (Kaplan et al., 1964; Kune, 1968; Nugent and Zuberi, 1968; Jordan and Spjut, 1972) are only approximations. Of the 30 deaths in our series, 23 (76·7 per cent) had haemorrhagic pancreatitis. Since we had operated on about half of our patients during the acute attack (and operation was performed on those with severe disease), and since the incidence of operative diagnosis of haemorrhagic pancreatitis was only 14·8 per cent, it would appear that in our community the incidence of haemorrhagic pancreatitis is unlikely to exceed 10–15 per cent, which is within the range of 10–25 per cent estimated by Glazer (1975).

Operative management

We operated on 54·3 per cent of our patients in the acute phase because of the high incidence of biliary tract disease, especially the condition of recurrent pyogenic cholangitis (Ong, 1968), among the indigenous population. Many of these patients presented with or developed septicaemic shock from cholangitis. In addition, 12·5 per cent of the patients with recurrent pyogenic cholangitis also had pancreatitis. Thus, even when a diagnosis of acute pancreatitis is established biochemically, if there is any suspicion of cholangitis, such as jaundice, fever or chills, early surgical intervention is mandatory. When the serum amylase is not raised and cholangitis is suspected, the need for early operation is even more urgent as all the clinical features may be attributable to cholangitis. It is also our belief that when acute pancreatitis is associated with ductal stones, decompression of the bile duct may minimize the severity or reverse the progression of the disease. For these reasons, early operation was our choice of treatment unless the disease was clinically mild, there was a strong probability that alcohol was the cause or biliary tract disease could reasonably be excluded.

Common duct exploration was the procedure most frequently performed (57·4 per cent) and the mortality of this procedure did not differ from that of laparotomy alone. Although we were reluctant to perform sphincteroplasty in the acute phase because of the many recognized hazards (Anderson, 1965; Louw et al., 1967; Trapnell, 1972), this operation was carried out in 19 patients without complications or deaths. In each instance a stone was impacted at the ampulla, and we believe, as do Salzman and Bartlett (1963), that under these circumstances this operation is essential and can be performed without added risk to the patient.

Pancreatectomy for acute haemorrhagic pancreatitis has been advocated by Watts (1963), Hollender et al. (1969) and Guivarch et al. (1972). Although this is a severe operation in a critically ill patient, removal of the necrotic gland may offer these patients a small chance of recovery since the mortality of other forms of treatment is equally prohibitive. The rapid clinical improvement of the one patient in this series who survived subtotal pancreatectomy may indicate that in selected patients this course of treatment
appropriate one.

Our mortality rate in the operated gro
per cent is substantially higher than that i
operated group (3·5 per cent). This mort
though lower than that reported by Trap
and Imrie (1974), could probably be reduc
patients without biliary tract diseases we
conservatively. The total number of patie
series who underwent operations (emerg
elective) was 225 (72·3 per cent) which is 6
cent) more than the total number of pat
biliary tract disease. If this latter group
could be identified, they might have be
conservatively, so long as there were no ot
tions for operation. Since the association
tract diseases and alcoholic pancreatitis w
our patients, a definite history of alcoh
should be accepted as the only cause,
patients should be treated without operat
diagnosis can be established biochemically.

However, in spite of the large number of
the mortality rate is not unduly high. This
represents the small risk of operation (3·
mortality) when an oedematous gland is
agree with Trapnell's suggestion (1974) tha
tory laparotomy in acute pancreatitis is
lethal procedure as it was once thought. It
undertaken if the diagnosis is in doubt
patient's condition deteriorates in spite o
conservative measures. This principle has
advocated by Anderson (1965), Zimberg (
Glazer (1975).

Our results show that patients with bi
disease who refuse surgery almost invari
from further acute attacks. Although bi
surgery does not confer absolute immu
subsequent attacks, the risk of such
appears to be minimal. On the other ha
tract surgery offers no protection again
attack for alcoholic patients and patients
or unknown causes.

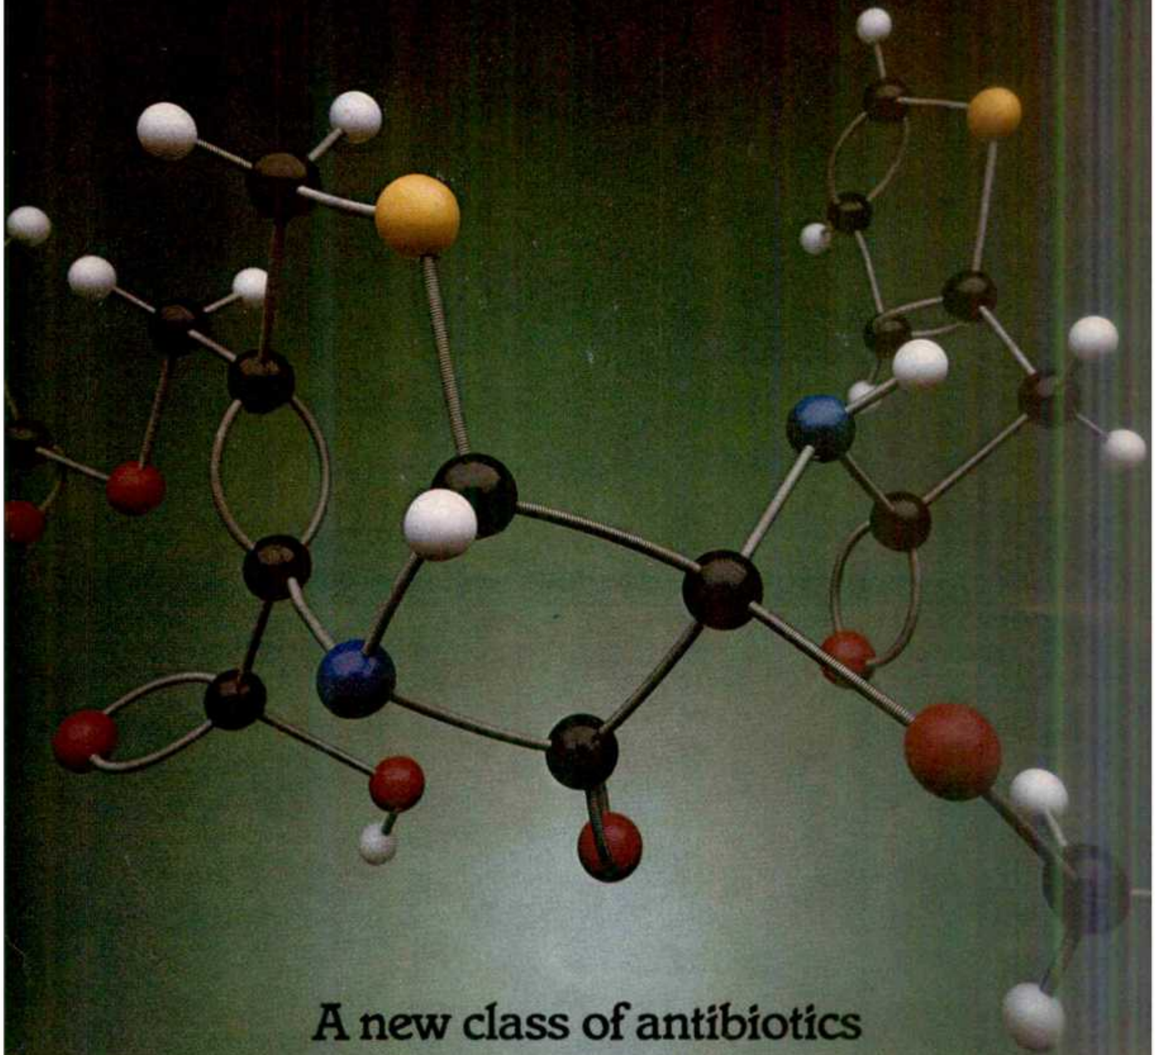
MSD announces
the discovery of

Mefoxin®

Cefoxitin sodium, MSD

INJECTION

First of the cephamycins



A new class of antibiotics

'Mefoxin' is derived from cephamycin C, a naturally occurring antibiotic substance produced by *Streptomyces lactamdurans*. This naturally occurring antibiotic has been modified in the MSD Research Laboratories to enhance its therapeutic usefulness.

Prescribing information overleaf

Outstanding clinical benefits

Wide-ranging activity against Gram-negative and Gram-positive pathogens, anaerobes as well as aerobes.

Unusually high resistance to β-lactamase degradation.

Highly active against *Bacteroides fragilis* and strains of *E.coli*, Serratia, Klebsiella spp. and Proteus spp. (including indole positive strains) resistant to other antibacterial agents.

Offers high levels of active antibiotic in the body.

A record of relative safety comparable to the penicillins.

Prime indications include:

- Peritonitis, and other intra-abdominal and intrapelvic infections.
- Female genital tract infections
- Septicaemia
- Skin and soft tissue infections
- Bone and joint infections
- Urinary tract infections
- Respiratory tract infections (e.g. inhalation pneumonia)

Specific clinical profile

'Mefoxin' is exceptionally valuable wherever Gram-negative pathogens and anaerobes are involved in mixed infections. When mixed infections are suspected, therapy may be started while awaiting the results of susceptibility testing.

Mefoxin®

Cefoxitin sodium, MSD

INJECTION

First of the cephamycins

the vein over a period of 3 to 5 minutes or may be given through the tubing when the patient is receiving parenteral solutions.

An intermittent intravenous infusion of 'Mefoxin' may be employed when large amounts of fluid are to be given. However, during infusion of the solution containing 'Mefoxin', it may be advisable temporarily to discontinue administration of any other infusion solution at the same site (by using an appropriate IV infusion set).

A solution of 'Mefoxin' may also be given by continuous intravenous infusion (see below for compatibility and stability).

Intramuscular administration ONLY

Reconstitute 'Mefoxin' 1 g with 2 ml of Water for Injection BP, or 0.5% or 1% lignocaine hydrochloride (without adrenaline) solution. 'Mefoxin' is given by deep injection into a large muscle mass. Avoid injection into a blood vessel.

Compatibility and stability

A solution of 'Mefoxin' in Water for Injection BP may be added to the following solutions: 0.9% Sodium Chloride Injection BP, 5% or 10% Dextrose Injection BP, Dextrose and Sodium Chloride Injection (5%/0.9%, 5%/0.45%, or 4.3%/0.18%), Lactated Ringer's Injection USP, 5% Dextrose in Lactated Ringer's Injection, 5% or 10% invert sugar in water, 10% invert sugar in saline solution, 4.2% Sodium Bicarbonate Injection BP, M/6 Sodium Lactate Injection BP.

'Mefoxin', as constuted to 1 g 10 ml with Water for Injection BP, Water for Injection BP preserved with parabens or benzyl alcohol, 0.9% Sodium Chloride Injection BP, or 5% Dextrose Injection BP, maintains satisfactory potency for 24 hours at room temperature, for 96 hours under refrigeration, and for 13 weeks in the frozen state.

'Mefoxin' can be administered concomitantly with such antibiotics as gentamicin, tobramycin, carbenicillin or amikacin. When 'Mefoxin' is administered with another antibiotic, they should not be mixed in the same syringe.

Contra-indications

'Mefoxin' is contra-indicated in persons who have shown hypersensitivity to cefoxitin. In the absence of clinical experience, 'Mefoxin' should not be administered to patients who have shown hypersensitivity to cephalosporins.

Precautions

There is some clinical and laboratory evidence of partial cross-allergenicity between cephamycins and other β-lactam antibiotics, penicillins, and cephalosporins. Severe reactions (including anaphylaxis) have been reported with most β-lactam antibiotics.

Before therapy with 'Mefoxin', careful inquiry should be made concerning previous hypersensitivity reactions to β-lactam antibiotics. 'Mefoxin' should be given cautiously to penicillin-allergic patients.

Any patient who has demonstrated some form of allergy, particularly to drugs, should receive antibiotics cautiously. If an allergic reaction to 'Mefoxin' occurs, the drug should be discontinued.

The total daily dosage should be reduced when 'Mefoxin' is administered to patients with transient or persistent reduction of urinary output due to renal insufficiency (see 'Dosage and administration') because high and prolonged serum antibiotic concentrations can occur from usual doses.

Interference with laboratory tests

A false-positive reaction to glucose in the urine may occur with reducing substances but not with the use of specific glucose oxidase methods.

Use in pregnancy

Use of the drug in women of childbearing potential requires that the anticipated benefits be weighed against possible hazards. Reproductive and teratogenic studies have been performed in mice and rats and have revealed no evidence of impaired fertility or harm to the foetus due to 'Mefoxin'. There are no controlled studies with 'Mefoxin' in pregnant women.

Nursing mothers

'Mefoxin' is excreted in human milk.

Infants and children

Pending the outcome of clinical trials in progress, the conditions for use of 'Mefoxin' in infants and children remain to be defined.

Side effects

'Mefoxin' is generally well tolerated. Side effects rarely require stopping treatment and usually have been mild or transient.

Local reactions

Thrombophlebitis has occurred with intravenous administration. Pain induration and tenderness after intramuscular injections have been reported.

Allergic

Maculopapular rash, urticaria, pruritus, [illegible] and other allergic reactions have been noted rarely.

Gastro-intestinal

Diarrhoea has been reported rarely.

Blood

Transient leucopenia and neutropenia have been reported. Some individuals, particularly those with [illegible] positive direct Coombs tests during therapy [illegible]

Liver function

Transient elevations [illegible] alkaline phosphatase have been reported rarely.

Kidney

Elevations in serum creatinine and/or [illegible] been observed. The role of 'Mefoxin' in changes [illegible] is difficult to assess, since factors predisposing [illegible] or to impaired renal function usually have [illegible]

Presentation

In vials containing 1 g or 2 g of cefoxitin [illegible] gram of cefoxitin contains approximately [illegible] sodium.

Product licence numbers: 1 g 0025/[illegible]

Product authorisation numbers: 1 g [illegible]

Issued October 1978

Additional information is available to the medical profession on request.

Basic NHS cost is £4.47 [illegible] the 1 g vial [illegible] 94 for the 2 g vial.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Haemorrhagic cholecystitis

V. R. SHAH AND J. F. CLEGG*

SUMMARY

Two cases of haemobilia due to haemorrhagic cholecystitis are presented; only 28 other cases have been described. As there are so many more dramatic causes and treatment for haemobilia it is important for the surgeon to recognize that a common operation will suffice for this rare condition. In both cases bacteria were grown from the bile and it is to be hoped that bile culture will be recorded more commonly in future in cases of this interesting condition.

GASTROINTESTINAL haemorrhage is a very common emergency, but rarely is bleeding found to originate from the biliary tract (Manfredi, 1958). The most common causes of haemobilia these days are hepatic trauma and tumour of the liver and bile ducts. Sandblom (1972), via the world literature of haemobilia, found that the inflammatory causes of haemobilia accounted for only 13 per cent of cases and gallstones were implicated in 14·9 per cent of the series. Inflammatory causes include ascariasis (Ch'en Shu Chen, 1963), tuberculosis (Agrawal, 1967), hydatid disease (Goulston, 1955), sclerosing cholangitis (Larmi, 1966) and hepatic abscess (Urschel, 1963). Haemorrhagic cholecystitis, whether associated with gallstones or not, is a rare cause of haemobilia and gastrointestinal haemorrhage.

To date, 28 cases of haemorrhagic cholecystitis have been recorded in the world literature. In this paper we discuss the details of 2 further cases.

Case reports

Case 1: This man, a German electrical engineer, was admitted as an emergency on 12 May 1977 with a history of colicky upper abdominal pain for 1 day. The pain was severe and radiated to the front of his chest, causing him some difficulty in breathing. He gave a previous history of fatty food intolerance and his urine was noted to be dark. There was no previous history of jaundice.

Previously he had had an episode of probable biliary colic in 1973 and he had also had a splenectomy for traumatic rupture of the spleen in 1950.

On examination he was in severe pain. He had a pyrexia of 38·5 °C; the pulse rate was 72/min and regular. The blood pressure was 140/90 mmHg. In the abdomen there was tenderness and guarding in the right hypochondrium.

Investigations revealed the urine to contain bile. Other findings were: haemoglobin 15·9 g/dl; white cell count 9×10^9/l; bilirubin 126 μmol/l; alkaline phosphatase 17 KA units; prothrombin time 14 s; serum amylase 100 Somagyi units; aspartate transaminase 188 i.u.; faecal occult blood positive. Ultrasonic scan of the liver revealed distension of the intrahepatic and extrahepatic bile ducts including the gallbladder suggestive of an obstruction of the common bile duct.

Following admission, the patient developed deepening jaundice together with further attacks of biliary colic and pyrexia. Despite the absence of rigors he was thought to have cholangitis and on the day before operation he developed frank melaena.

At operation on 17 May 1977 gastroendoscopy was performed. This revealed no abnormality in the oesophagus, stomach or duodenum. A cholecystectomy and exploration of the common bile duct was performed.

The gallbladder was grossly distended and adherent to the liver and omentum. The wall was thick and inflamed and full of blood but no gallstones were present. Bleeding was arising from the inflamed epithelial lining of the gallbladder. The common bile duct was normal in size and contained clear bile. No abnormality could be found in the porta hepatis and an operative cholangiogram via the cystic duct was normal.

Histology of the gallbladder revealed evidence of mucosal and submucosal haemorrhage. In the external fat there was young fibrous tissue with some oedema. Bile from the gallbladder grew *Enterobactericae sporogenes.*

Following the operation the patient made a very satisfactory recovery and was discharged home. He has remained well during the subsequent year.

Case 2: This 58-year-old lady was admitted on 18 August 1972 with a 1-week history of pain in the epigastrium and right hypochondrium associated with vomiting. She had previously had six similar attacks over the previous 5 years. There was no history of jaundice but she had had fatty food intolerance.

On examination she was pyrexial (38 °C); her pulse rate was 100/min and blood pressure 160/100 mmHg. Abdominal examination revealed tenderness and guarding in the right hypochondrium. No mass was palpable.

Investigations carried out on admission revealed a serum bilirubin of 19 μmol/l, serum alkaline phosphatase of 18 KA units and serum albumin of 41 g/l. Serum globulin was 2·9 g/l and SGOT was 40 i.u. Double-dose cholecystography failed to visualize the gallbladder. Haemoglobin was 12·5 g/dl, white cell count 13×10^9/l, serum amylase 150 Somagyi units and prothrombin time 15 s.

A diagnosis of cholecystitis was made and arrangements were made for operation. However, 6 hours before operation the patient had a frank haematemesis and passed a melaena stool. At laparotomy a grossly inflamed gallbladder was found to be stuck to surrounding structures. The gallbladder was full of blood and contained stones. The common bile duct was dilated and contained blood clot, as did the stomach and duodenum.

A cholecystectomy and exploration of the common bile duct was performed together with liver biopsy. Bile culture grew pneumococci.

Following operation the patient made a good recovery and a subsequent T tube cholangiogram was within normal limits. There were no further episodes of haematemesis and melaena and the patient is well 5 years later.

Discussion

Most upper gastrointestinal bleeding arises in the oesophagus, stomach or duodenum. When a diagnostic study of this region is negative, it is well to keep in mind the possibility of haemobilia. If haemorrhage occurs in the gallbladder, several possibilities may arise. First, the blood may clot in the gallbladder, in which case the gallbladder will enlarge. Secondly, the blood may pass into the common bile duct and then into the duodenum causing either haematemesis or melaena. If the blood clots in the bile ducts, obstructive jaundice may occur with attacks of biliary colic. In certain cases of haemorrhagic cholecystitis the enlarged gallbladder has ruptured into the peritoneal cavity (Polse et al., 1976). It is surprising that haemorrhagic cholecystitis is so rare, as Gad (1962) examined a large series of patients with cholelithiasis and found 25 per cent of them to have a positive faecal occult blood.

Quincke (1871) described a diagnostic triad for haemobilia consisting of biliary colic, gastrointestinal haemorrhage and jaundice. Unfortunately, if the cause of the haemobilia is haemorrhagic cholecystitis, this useful triad is often overlooked, as in our 2 cases, because the patient initially presents with acute cholecystitis and the gastrointestinal haemorrhage comes as a secondary phenomenon. In our 2 cases, both patients were thought to have stress ulceration, and indeed in our second case the patient had a gastroduodenal endoscopy for this specific reason; no source for the bleeding was found. Nevertheless, it might have shown blood issuing from the ampulla of Vater and this investigation is always worthwhile in any case of gastrointestinal haemorrhage.

---

* Leighton Hospital, Leighton, Crewe.
Correspondence to: J. F. Clegg.

If haemobilia is considered a possible diagnosis for gastrointestinal bleeding, the correct preoperative investigation is selective hepatic artery angiography, as this may accurately localize the source of the bleeding and exclude the more common causes of haemobilia such as hepatic artery aneurysms or hepatic tumour. Unfortunately, this particular investigation has never been performed in any reported case of haemorrhagic cholecystitis and was not carried out in our 2 patients, the reason being that the diagnosis was not made preoperatively. Fortunately, in haemorrhagic cholecystitis the diagnosis is obvious at operation on opening the gallbladder and cholecystectomy will cure the condition. In our cases the common bile duct was explored and this seems to be a wise manoeuvre, as in *Case* 2 the common bile duct was obstructed by the presence of blood clots and, of course, these could be removed during the course of exploration. In the first case the common bile duct was explored despite a normal cholangiogram to make absolutely certain that there was no small bleeding point within the common bile duct.

In the case associated with gallstones pneumococci were isolated from bile culture. This is an unusual organism to be present in bile, as bile acids are bactericidal to the pneumococcus. However, if the concentration of the bile salts is high, as in the concentrated bile in the gallbladder, then this bactericidal property is lost due to aggregation of bile salt molecules and the organism can survive. The presence of this organism with the gallstones was possibly an important cause of the haemorrhagic ulceration of the gallbladder mucosa, as in the lung it can cause a haemorrhagic form of inflammation. Nevertheless, this particular organism has not been associated with the other cases of haemorrhagic cholecystitis in the world literature; unfortunately, bile culture has only been recorded on very few occasions previously. The other case which was not associated with the presence of gallstones in the gallbladder had *Enterobactericae sporogenes* cultured from the bile. This is a much more common organism in the biliary tree and probably infects the gallbladder in an ascending manner, whereas the mode of infection with the pneumococcus is probably haematogenous.

Primary hydatid cyst of the gallbladder

A. M. RIGAS, G. M. KARATZAS, N. C. MARKIDIS, D. S. BONIKOS, G. G. SOTIROPOULOU AND G. SKALKEAS*

SUMMARY

An unusual case of hydatid cyst of the gallbladder is presented. The difficulties in diagnosis are discussed. There is no other report of such a cyst in the world literature.

HYDATID disease is common in Greece. In a population of 10 000 000, approximately 500 patients are operated upon every year. Occasionally the disease is difficult to diagnose before operation. One such case is presented.

Case report

A 65-year-old woman was admitted in April 1978 with a history of intermittent pain in the right hypochondrium, radiating to the back, and vomiting. There was no anaemia, cyanosis, jaundice, oedema, ascites or lymphadenopathy. The liver and spleen were not felt. On investigation the haemoglobin was 13 g/dl, the blood urea was 6·6 mol/l and the liver function tests were normal.

Barium meal and barium enema examinations and chest X-rays were normal. A cholangiogram revealed a common bile duct of normal calibre without stones; the gallbladder shape was abnormal with a filling defect (*Fig.* 1). The liver scan was within normal limits. A presumptive diagnosis of gallstones or a gallbladder anomaly was made.

Exploratory laparotomy revealed a cyst of the body of the gallbladder and cholocystectomy (including the cyst) was performed. There was no other hydatid cyst detected in the abdomen. The patient was discharged on the ninth postoperative day and has remained well since.

The gallbladder specimen measured 8×4 cm in its greatest dimensions and it had a thick wall. There was an ovoid thin-walled cyst measuring 5×4 cm loosely attached to the external surface of the body of the gallbladder. The cyst contained numerous thin, white, soft concentric membranes (*Fig.* 2). The appearance suggested a diagnosis of an echinococcal cyst, which was confirmed on microscopic examination. There was no significant histopathological abnormality of the gallbladder, which did not communicate with the cyst.

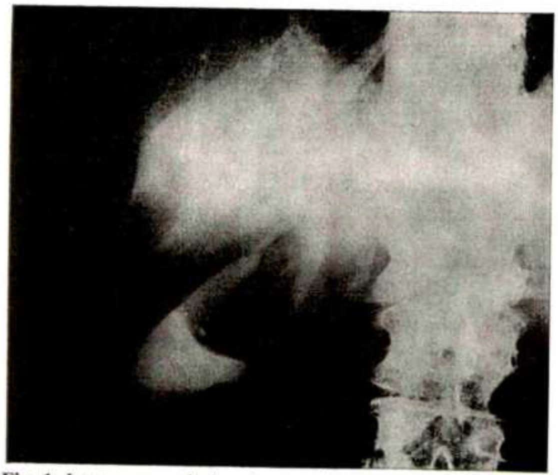

Fig. 1. Intravenous cholangiogram showing a common bile duct of normal calibre but the gallbladder has an abnormal shape.

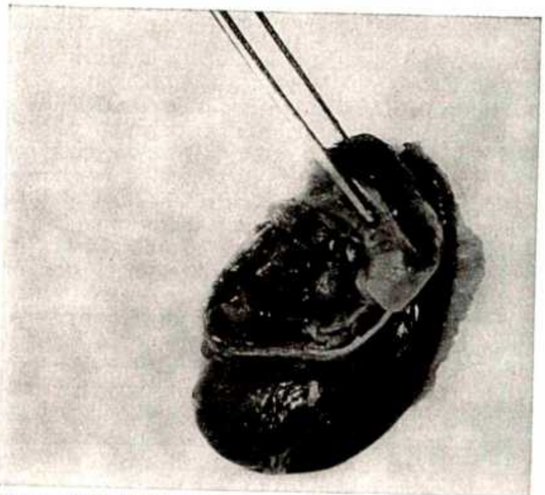

Fig. 2. Opened hydatid cyst: note the membranes arranged in a concentric laminated fashion.

Discussion

The most frequent site of hydatid disease is the liver because it is the first filter of parasitic embryos migrating from the intestine. The incidence of disease at this site varies from 60·3 per cent (Kourias, 1974) to 93 per cent (Emamy and Asadian, 1976; Jones, 1978).

A review of more than 14 000 cases of hydatid disease in Greece did not include any case of hydatid cyst of the gallbladder (Prokos et al., 1964). No other report of such a cyst has been found in the world literature. It is usually only large cysts that produce symptoms. In our case the size of the cyst was small (5×4 cm approximately) and the symptoms suggested possible gallstones because of some derangement of function of the gallbladder.

The probable mode of spread of the parasitic embryo to the gallbladder was from the gut via the lymphatics. In our case total excision of the cyst, the ideal procedure for any hydatid cyst, was feasible because it was attached to the gallbladder wall.

Splenic cysts: a review of 6 cases

W. G. HUMPHREYS AND G. W. JOHNSTON*

SUMMARY

Benign cysts of the spleen are rare. Six cases have been managed in this hospital in the past 25 years. The history, physical findings and investigations are reviewed. It is suggested that splenectomy is the treatment of choice as it carries a low morbidity and mortality.

WITH the increasing incidence of road traffic and sporting accidents, the spleen has become the most frequently injured intra-abdominal organ in cases of closed trauma. There is little argument that immediate splenectomy is the treatment of choice for the acutely ruptured spleen, since delayed diagnosis and the surgery of delayed rupture have a high morbidity and significant mortality (Zabinski and Harkins, 1943). Douville and Bélanger (1972) reported that delayed rupture of the spleen may occur in up to 14 per cent of all cases of splenic injury, but the development of a splenic pseudocyst is a rare late complication of splenic trauma (Halvorsen et al., 1974).

This report was prompted by the recent management of 4 such cases in one surgical unit. Review of the hospital records produced only 2 further cases in the previous 25 years, and all 6 are reported here.

Case reports

Case 1: A 16-year-old male was thrown from his motorcycle and sustained an injury to his left upper abdomen, but he did not require hospitalization. One year later, he presented with a dull ache in his left hypochondrium and a mass in the left upper abdomen was obvious on inspection and palpation. The clinical and ulrasonographic diagnosis was traumatic pancreatic pseudocyst, but at laparotomy a large splenic cyst was found. After splenectomy there was an uneventful recovery with alleviation of the patient's symptoms.

Case 2: A 41-year old male who was involved in a road traffic accident sustained blunt trauma to the abdomen and was admitted with left-sided upper abdominal pain and haematuria. A palpable mass in the left hypochondrium and left loin was thought to be a perirenal haematoma. Intravenous urography confirmed a small left renal capsular rupture. On conservative management the pain and haematuria resolved but a cystic mass persisted in the abdomen. Renal arteriography showed normal renal vasculature, but selective coeliac angiography demonstrated the presence of a splenic cyst. As yet, this patient has not had surgical intervention.

Case 3: A 24-year-old female presented with a history of abdominal swelling for 1 year and left hypochondrial pain for 4 months. There was no relevant past history and the only positive physical finding was splenomegaly. A preoperative diagnosis of splenic cyst was made from the liver scan, ultrasonography and renal tomography. At laparotomy a unilocular splenic cyst 18 cm in diameter and 1600 g in weight was removed. The patient's postoperative course was uncomplicated.

Case 4: A 58-year-old female was admitted with a 1-month history of anaemia, weakness and vague upper abdominal pain. Examination revealed a mass in the left hypochondrium which was shown by scintiscan, barium meal examination and ultrasonography to be of splenic origin. It was noted that at 12 years of age she had fallen from her bicycle and had sustained fractured ribs on the left side. At operation a cyst 25 cm in diameter was removed with splenectomy The patient's operative course was satisfactory and her anaemia improved. Histologically, this was a simple cyst, probably of traumatic origin.

Case 5: A 16-year-old girl was readmitted 4 months after appendicectomy with a history of left shoulder-tip pain and a mass in the left hypochondrium. Barium meal examination and pyelography demonstrated splenic enlargement and a splenic portogram showed a cyst of the spleen 18 cm in diameter. The diagnosis was confirmed at surgery when a 1500-g mass was removed. Histology showed a simple unilocular cyst and normal splenic tissue. The girl remains well.

Case 6: A 50-year-old man was referred with a short history of pain in the left hypochondrium. In the past he had sustained blunt upper abdominal trauma. On plain X-ray of the abdomen a calcified lesion was noted in the left hypochondrium. This was shown to be extrarenal on pyelography and to be cystic on ultrasonography. It was thought to be an adrenal cyst, but at laparotomy a calcified splenic cyst 5 cm in diameter and 180 g in weight was removed by splenectomy. The patient's subsequent progress was satisfactory.

Discussion

Splenic cysts are rare and it is unusual for a physician or surgeon to see many such cases in his clinical practice (Topilow and Steinhoff, 1975). The cysts probably arise as the result of organization and liquefaction of a subcapsular haematoma of the spleen.

Since the original description of this lesion by Andral in 1829, fewer than 600 cases of non-parasitic benign splenic cyst have been reported in the world literature (Robbins et al., 1978), mainly in three large collected series (Fowler, 1953; Posener and Litherland, 1956; Qureshi et al., 1964). According to Qureshi and Hafner (1965), accurate preoperative diagnosis has been rare, but a high index of suspicion allied to careful investigation should reverse this unsatisfactory situation.

All patients in this series had a classic history of left hypochondrial pain with a palpable mass. In two-thirds of the cases there was a history of past trauma. Symptoms were present for a mean period of 18½ months before investigation and this delay is typical of that reported by others (Grosdidier et al., 1974). The density of the lesion may be demonstrated by ultrasonography or CAT scan and the position of the mass relative to the left kidney can be demonstrated by pyelography and selective angiography. Splenectomy is indicated to alleviate pain, remove the mass and obviate the risks of infection or late rupture. In the 5 patients submitted to laparotomy and splenectomy, the splenic lesions were histologically simple cysts with a mean diameter of 15·9 cm (range 5·5–20 cm) and a mean weight (combined with the spleen) of 1375 g (range 180–3000 g). The outcome was favourable in all cases and the sixth patient is asymptomatic but remains under review.

Acknowledgements

We wish to thank our colleagues who referred their patients for investigation and surgery, and we are grateful to Mr E. Morrison, Mr. J. W. S. Irwin and Dr J. S. Logan for permission to publish the case histories of their patients.

The Royal College of Surgeons of Edinburgh: Endowment Fund Appeal

The Royal College of Surgeons of Edinburgh has launched a world-wide, public appeal to set up an endowment fund. In explaining the purpose of this appeal the President, Professor Andrew Wilkinson, writes:

> In the past, the financial independence of the College and the services which it provides have depended on the subscriptions paid by its Fellows and from investments. There has never been an endowment fund and the College has never in its 473 years appealed for money.
>
> If the College is to continue as a leading centre of surgical education however, it is essential that its teaching programmes and related activities are not curtailed through lack of space. At present the financial state of the College is good but, to achieve its aims and to ensure its financial stability and development, an endowment fund of £1·5 m is needed.

Some of the money which it is hoped will be raised will be used to provide living accommodation for surgeons in training and for surgeons visiting Edinburgh for further study and experience. It is also intended to provide extra space for the library, and rooms for examinations and scientific meetings. Nearly £600 000 has already been contributed, largely by support from the College's Fellows and Licentiates in 92 countries, and the Council has now decided to broaden the scope of the appeal.

In a special appeal message, HRH The Prince Philip, Duke of Edinburgh, who is Patron and an Honorary Fellow of the College, writes:

> During the four hundred and seventy-three years since King James IV granted a Royal Charter, the Royal College of Surgeons of Edinburgh has set and enforced the most stringent conditions for those wishing to qualify as surgeons and it has succeeded in maintaining the highest standards of professional conduct among its Fellows. Today, three-quarters of its ten thousand Fellows are practising outside the British Isles and in every continent of the world.
>
> The long experience and traditions of the Royal College are so highly valued that young men and women from overseas are pressing to come to Edinburgh to study their craft, and the services they will be able to render their own people when they get home is a measure of the contribution the Royal College of Surgeons of Edinburgh is making to the welfare of mankind.

H_2-antagonists in the treatment of recurrent ulceration after vagotomy

C. G. CLARK, P. B. BOULOS, S. J. HAGGIE AND A. M. McDONALD*

SUMMARY

Twenty-two patients with recurrent ulceration following vagotomy with and without a drainage procedure have been treated with histamine H_2-antagonists and followed for up to 3 years. Four of a group of 6 patients responded to a single therapeutic course. Ten of 16 patients assigned to long term maintenance treatment remain symptom-free. Cimetidine may be an alternative to further surgery in the treatment of some patients with recurrent ulceration after vagotomy.

CIMETIDINE is an effective drug in the treatment of duodenal ulceration (Winship, 1978). The symptomatic (Haggie et al., 1976) and endoscopic (Wyllie, 1978) relapse rate is high when active treatment is discontinued, and it has become clear that once the ulcer has healed, maintenance therapy is required to prevent recurrence. How long maintenance treatment can be given is at present a matter of conjecture, but observations in patients treated in this way for up to 1 year appear to show considerable therapeutic success (Bodemar and Walan, 1978; Gudmand-Hoyer et al., 1978).

Recurrent ulceration after vagotomy for duodenal ulceration, with or without a drainage procedure, is not uncommon (Goligher et al., 1978). It is often regarded as more resistant to medical management than the original ulcer (Balint et al., 1957). The only effective treatment is further surgery, which many patients are reluctant to accept if some suitable alternative is available. Observations have been made on the value and limitations of H_2-antagonists in the treatment of patients with recurrent ulceration after vagotomy.

Patients and methods

Twenty-two patients with recurrent ulceration after vagotomy have been treated over a period of 3 years. Their ages ranged from 25 to 67 years, and there were 2 female patients. In all cases the original ulcer was in the duodenum. In 14 patients the operation performed was proximal gastric vagotomy (highly selective vagotomy) and in the remainder, vagotomy and pyloroplasty (4 truncal, 4 selective vagotomy). In 21 patients the diagnosis of recurrent ulceration was confirmed on endoscopy, one ulcer being situated in the prepyloric region and the remainder in the duodenum. In one patient endoscopy was contraindicated because of pre-senile dementia, but the recurrence (after proximal gastric vagotomy) was confirmed by barium meal examination. In all patients plasma gastrin estimations were made to exclude the Zollinger–Ellison syndrome.

Three patients were treated with metiamide until the drug was withdrawn from use, and the remainder were treated with cimetidine. The first 6 patients were treated with a dose of 200 mg three times daily and 400 mg at night for periods of 6–8 weeks, the aim being to achieve an asymptomatic state for 4 weeks. Thereafter no further treatment was given. By this time we had come to appreciate the limitations of a single therapeutic course of cimetidine in the treatment of duodenal ulceration and the need for some form of maintenance therapy. All subsequent patients were therefore treated with an initial therapeutic regimen of 1 g/day for 6 weeks followed by maintenance dosage of 400 mg at night. In one patient treatment was inadvertently given for 8 weeks, and in another patient treatment was extended for a further 6 weeks without success.

Only 12 patients had repeated endoscopy as part of their assessment, the investigation being accepted as necessary by those with persistent or recurrent symptoms, but generally refused by patients who were asymptomatic. Many of these patients had previously been involved with clinical trials of H_2-antagonists with repeated endoscopy for assessment, hence the difficulty in persuading asymptomatic patients into further endoscopy.

Results

Tables I and II summarize the results, the groups of patients being determined by the type of treatment and the outcome. There were 6 patients (*Table I*) treated at the beginning of the study with a single treatment regimen of 1·0 g of either metiamide or cimetidine for 6–8 weeks, excepting one patient whose treatment was continued for 16 weeks. The duration of treatment was determined by the time taken to control symptoms, but none of these patients was given maintenance treatment. Four patients have remained asymptomatic for 1–2½ years, though none of them has had further endoscopy. In 2 of the asymptomatic patients the recurrent ulcer may have been induced by ingestion of aspirin or phenylbutazone. Two patients in this group developed symptomatic recurrence at 1 and 2 years respectively, and both showed recurrent duodenal ulcers on endoscopy. Both patients have subsequently responded symptomatically to further treatment with cimetidine, including maintenance treatment.

There were 16 patients with recurrent ulceration for whom the proposed treatment was cimetidine 1·0 g/day for 6 weeks, followed by maintenance therapy of 400 mg at night. *Table II* shows that 10 patients remain symptom-free on this regimen for periods of 9–21 months, and in 8 endoscopy has confirmed healing. One patient relapsed on inadvertently stopping treatment but responded to further cimetidine. There were 6 treatment failures, 3 of these were recurrences in patients on maintenance treatment and 2 of these have subsequently been treated by operation. In 2 patients the ulcers failed to heal on the treatment regimen and these patients were treated by partial gastrectomy. The remaining patient responded symptomatically to cimetidine but on the fourth week of treatment was admitted with a massive haemorrhage and treated by emergency partial gastrectomy.

Discussion

These observations attempt to assess the potential value of H_2-antagonists in the treatment of recurrent ulceration after vagotomy. The aetiology of the recurrence has not always been investigated, and only a

PGV, Proximal gastric vagotomy; SV+P, selective vagotomy and pyloroplasty; TV+P, truncal vagotomy and pyloroplasty.

limited number of secretion studies have so far been performed. It may well be that the cause of recurrent ulceration differs with proximal gastric vagotomy compared with vagotomy and pyloroplasty. The basal fasting serum gastrin levels were all less than 120 pg/ml, and although no calcium- or secretin-stimulation tests were performed, it seems unlikely that any of the patients suffered from the Zollinger–Ellison syndrome, although this cannot absolutely be excluded (Deveney et al., 1977). Nevertheless, in the treatment of a patient with recurrent ulceration after any type of vagotomy, the choice lies between further surgery or drug therapy. Hitherto, treatment with drugs has generally been unsatisfactory and not without risk (Everson and Allen, 1954; Beal, 1959). Stabile and Passaro (1976), in a detailed review, calculated a mortality of 10·8 per cent and a relapse rate of 42·1 per cent in patients on medical treatment.

The diagnosis of recurrent ulceration was made by barium meal examination in one patient and by endoscopy in the remainder. The response to treatment has been judged on the basis of symptoms. In all patients who failed to respond to treatment or who subsequently relapsed, ulceration has been confirmed by endoscopy or at operation. It is recognized that ulcers may persist in a few asymptomatic patients (Burland et al., 1978) and this occurred in the patient admitted with haemorrhage. Therefore, the number of asymptomatic patients overestimates the number of healed ulcers.

In *Table I* 4 of the 6 patients responded to a single therapeutic course of cimetidine, an unusual event in the light of subsequent experience. A partial explanation may be that the ulcer may have been drug-induced (aspirin, phenylbutazone) and withdrawal of the drug may have been more beneficial than treatment with cimetidine.

Of the 16 patients who were entered into a therapeutic uncontrolled trial of cimetidine with maintenance treatment, 10 (62·5 per cent) have continued symptom-free for periods of 9–21 months. Delle Fave et al. (1977) noted that 9 of his 10 patients with recurrent ulceration following gastrectomy had healed within 2 months. Hoare et al. (1978) found in 17 of their 20 patients that the ulcer had healed at 6 weeks and Wastell et al. (1978) found that 4 of their 8 patients with recurrence after proximal gastric vagotomy had healed at 6 weeks. Saunders et al. (1978) have treated 13 patients with recurrent ulceration after surgery with full dosage (1 g/day) of cimetidine for 1 year, and of these, 10 healed within 1 month, 2 within 3 months and the other patients only after increasing the dosage to 1·6 g/day. Three recurrences were found during treatment (23 per cent), and after stopping treatment 3 patients remained well for more than 7 months.

Although Kennedy and Spencer (1978), in a controlled clinical trial in 12 patients using cimetidine versus placebo, found no significant difference in the rate of healing at 6 weeks, the present evidence indicates a therapeutic role of H_2-antagonists in the treatment of recurrent ulceration after gastric surgery. The majority of recurrent ulcers heal with a therapeutic course of 6 weeks' duration, though in some patients increased dosage or more prolonged treatment may be required. Cessation of treatment is not necessarily followed by relapse, but maintenance therapy is almost certainly desirable. The question which cannot yet be answered is: 'How long should treatment be continued?' It has been suggested that cimetidine should not be prescribed for more than a year because of the unknown effects of long term treatment (Leading Article, 1978). In the treatment of chronic duodenal ulceration cessation of maintenance treatment is frequently followed by relapse, and there is no reason to suppose that there will be any difference with recurrent ulcer. In these circumstances the only justification for treating recurrent ulceration with H_2-antagonists may be to 'buy time'.

The surgical treatment of recurrent ulceration is often technically difficult, with an operative mortality considerably greater than that of the initial operation. There may, therefore, be justification for treating such patients with cimetidine for prolonged periods, provided that adequate supervision is maintained.

The excretion of alkaline ribonuclease by children undergoing surgery

G. B. BARLOW, SUSAN H. WHITEAR AND A. W. WILKINSON*

SUMMARY

The excretion of alkaline ribonuclease has been measured in the urine of two groups of children after major operations. The excretion was significantly increased in all patients after open operations on the heart and in many of those who were operated on soon after birth for anomalies in the intestine. It is suggested that these elevations may indicate a disturbance of pancreatic function.

In adults severe pancreatitis has been observed after some kinds of cardiac operation. The condition has been attributed to the disturbance of the blood supply and is most common in patients who die (Feiner, 1976). Elevation of the concentrations of amylase in serum and of urine of up to ten times the normal level are taken as indications of pancreatitis and, following recovery, the amylase concentrations in both serum and urine rapidly return to within the normal range. Similar large increases in the serum amylase concentration may be observed during the first 2 days after operations on the chest and a moderate elevation may persist for several further days (Hennings and Jacobson, 1974).

It has been shown that three degrees of malnutrition in children can be recognized according to the concentrations of ribonuclease in the urine and serum (Sigulem et al., 1973). We have shown recently that the urinary output of ribonuclease may be greatly increased in children after injury by burning or scalding (Barlow and Whitear, 1977). We have, therefore, examined the urinary output of ribonuclease in two groups of children, one group having had open operations on the heart and the other, operative treatment soon after birth for various intestinal abnormalities.

Patients and methods

Urine was obtained from 6-hourly specimens collected postoperatively from 31 children for up to 16 days as part of a series of metabolic balance studies. The urine was collected into ion-free plastic bags (Hollister) and deep frozen without preservative until required for assay; urine can be stored frozen for up to 12 months without any effect on the enzyme activity. Control urine values were obtained from measurements in 13 children aged 10 months to 10 years who had been admitted to hospital for minor operations and from 3 normal neonates (21 occasions) and from 2 neonates with Beckwith's syndrome (4 occasions). Details of the patients, diagnoses and operations are shown in *Table I*.

The urinary alkaline ribonuclease activity was measured as described by Barlow and Whitear (1977).

Results

The output of ribonuclease in the 13 control children aged 10 months to 10 years was $0{\cdot}43 \pm 0{\cdot}29$ Kunitz units 24 h^{-1} kg^{-1} (mean ± s.d.), and in 25 single 24-h collections from neonates was $0{\cdot}52 \pm 0{\cdot}2$ Kunitz units 24 h^{-1} kg^{-1} (mean ± s.d.). The method had a coefficient of variation of 13·9 per cent.

After open heart operations excretion of ribonuclease in the urine was significantly raised for about 8 days and in some patients for even longer (*Table II*). The urinary excretion of ribonuclease, averaged over the period for which collections were made, was also increased in 14 out of 20 patients operated on soon after birth for intestinal anomalies. Even in 3 of those cases that did not show an overall increase there were several days when significantly high levels were observed. There was no correlation between urine volume and the excretion of the ribonuclease. Gaps in *Tables II* and *III* indicate that the ribonuclease activity was not measured on these days either because there were no urine collections made or because the collections were incomplete.

Table I: DETAILS OF THE CASE SERIES

Case no.	Age	Diagnosis and operation
1	4 mth	Ventricular septal defect; patent foramen ovale
2	4 d	Total anomalous pulmonary venous drainage
3	7 yr	Ventricular septal defect
4	23 d	Pulmonary stenosis
5	7 mth	Transposition of the great arteries; ventricular septal defect; patent ductus arterosis
6	6 mth	Transposition of the great arteries
7	9 mth	Transposition of the great arteries
8	5 mth	Transposition of the great arteries
9	14 d	Total anomalous pulmonary venous drainage; patent ductus arterosis; atrial septal defect
10	1 mth	Ventricular septal defect; aortic stenosis
11	14 d	Total anomalous pulmonary venous drainage
12	7 d	Oesophageal atresia and tracheo-oesophageal fistula
13	3 d	Oesophageal atresia and tracheo-oesophageal fistula
14	2 d	Tracheo-oesophageal fistula
15	2 d	Gastroschisis
16	14 d	Gastroschisis
17	3 d	Gastroschisis
18	2 d	Gastroschisis
19	2 d	Hirschsprung's disease
20	6 wk	Hirschsprung's disease
21	1 mth	Laparotomy: right cutaneous ureterostomy
22	10 mth	Laparotomy: colostomy
23	7 d	Laparotomy: necrotizing enterocolitis
24	5 d	Intestinal obstruction
25	1 mth	Intestinal obstruction
26	8 d	Ileal atresia
27	2 d	Ileal atresia; small bowel volvulus
28	10 wk	'Apple-peel' small bowel; multiple jejunal atresias
29	4 mth	Multiple small bowel adhesions
30	6 mth	Enteric duplication
31	6 d	Ladd's bands; malrotation of the mid-gut

The output of amylase was below the detectable limit (10 Somogyi units/day) in all controls and was detected at very low levels, far below the normal adult range, only on the first day in 4 patients after

open heart operation. *P* values were calculated using the mean of all the observations in the group.

Discussion

Although Sigulem et al. (1973) found that the output of ribonuclease in the urine of neonates was lower than in children aged 7 months or more, we found that when these outputs were expressed in terms of body weight and the duration of the period of collection there were no significant differences between the neonates less than 15 days old and children over 10 months of age except in one normal premature baby (31 weeks' gestation) who had an unexplained high output; the results from this baby were at least five standard deviations above the mean.

Regardless of what kind of open operation was done on the heart, all patients except the one with the transposition of the great arteries (*Case* 7) showed a raised output of ribonuclease in the urine when this was averaged out over the days of the collections. In the one exception, although there was not an increase, overall excretion was high on 5 of the 10 days on which collections were made. In the 3 other patients with transposition of the great arteries the urinary excretion was raised but not by as much as in other patients after cardiac operations. With the one exception, the difference between the ribonuclease outputs after cardiac operations and those of normal patients was significant ($P<0·001$). In cases with transposition of the great arteries the patient is often cyanosed, with a low Po_2, and, having had the condition for some time, may well have become adapted to some extent, so that on operation, the effect on the ribonuclease excretion would be less than otherwise. If the total urinary excretion of ribonuclease averaged over the days of collection in patients who had open operations on the heart is compared with that of patients who had been accidentally burned the severity of the cardiac operations varies between the equivalent of a burn of 20 per cent of the body surface (*Case* 7) and 80 per cent of the body surface (*Case* 9). This should not, however, be taken as an accurate index of the severity of the surgical injury suffered by the patients undergoing major open operations on the heart, as there are surely a number of other factors that might influence the urinary output of ribonuclease. Many heart operations are carried out at subnormal body temperature with reduced blood flow to the pancreas.

There were some marked differences in ribonuclease excretion in the group of patients who were treated for various malformations of the gastrointestinal tract. It is surprising that 2 of the 3 patients who were treated for oesophageal atresia with tracheo-oesophageal fistula did not show increased ribonuclease excretion, and the third showed only a slight elevation. There were, however, significant increases in output in 4 babies with gastroschisis and in 3 who underwent laparotomy for various causes ($P<0{\cdot}05$).

The ribonuclease found in these urine samples had an optimum pH of 7·8, which was identical in normal children and in those having had an operation. This pH is indicative of an exocrine digestive function compatible with a pancreatic origin. In adults, when pancreatic disturbance is suspected it is usual to measure also the serum or urinary amylase concentrations. Urinary amylase in children, as we have shown, is not usually detectable, and when it was found in this series it might have been due to morphine given for the operation.

Universal Tube Holder

From Downs Surgical.

British Patent No 1 471 609
Designed by Laurence F Tinckler MD, ChM, FRCS, FACS.

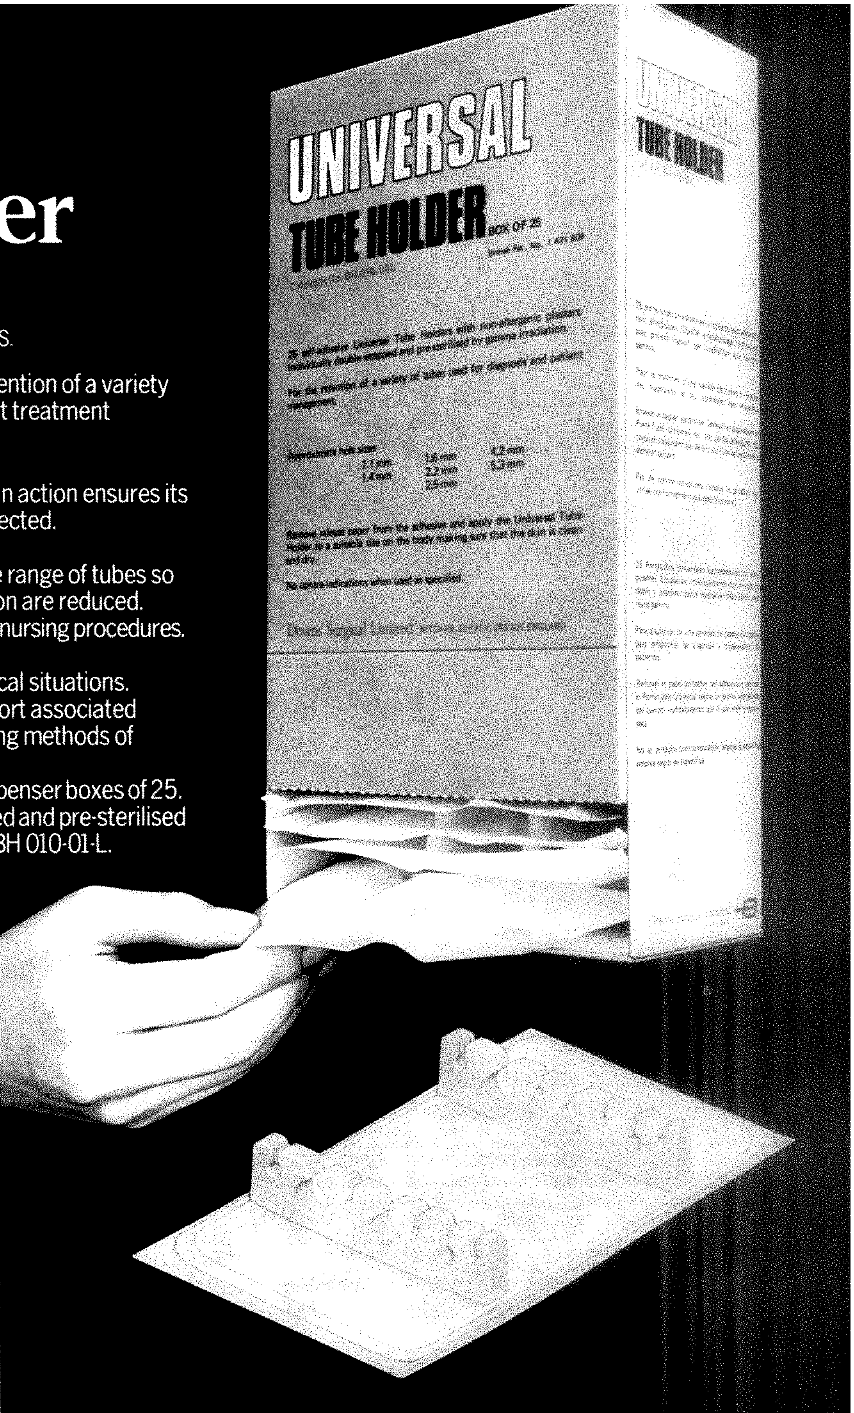
For the fast, convenient and comfortable retention of a variety of tubes, catheters and leads used for patient treatment and diagnosis.

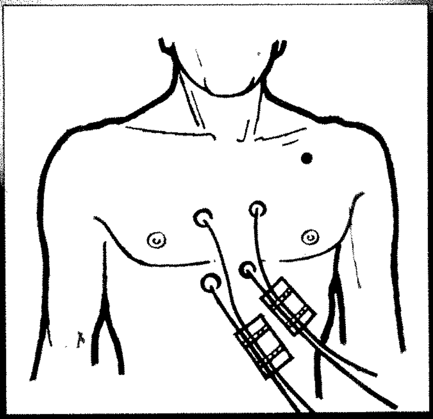
☐ **Fast:**
May be positioned immediately. Unique slot-in action ensures its easy application after tubes have been connected.

☐ **Convenient:**
Seven different slot sizes for retaining a wide range of tubes so that the risks of tension, kinking and occlusion are reduced. Tubes can be temporarily released to facilitate nursing procedures.

☐ **Comfortable:**
The flexible base conforms to most anatomical situations. Non-allergenic adhesive. Avoids the discomfort associated with bandages, strapping and anchor-suturing methods of tube retention.

The Universal Tube Holder is packaged in dispenser boxes of 25. Each Universal Tube Holder is double-wrapped and pre-sterilised by gamma irradiation. Catalogue reference BH 010-01-L.





Downs Surgical - simply the best

To: Disposable Products Division, Downs Surgical Limited, Church Path, Mitcham, Surrey, CR4 3UE, England.
Please send me further information and samples of the Universal Tube Holder.

SIEMENS

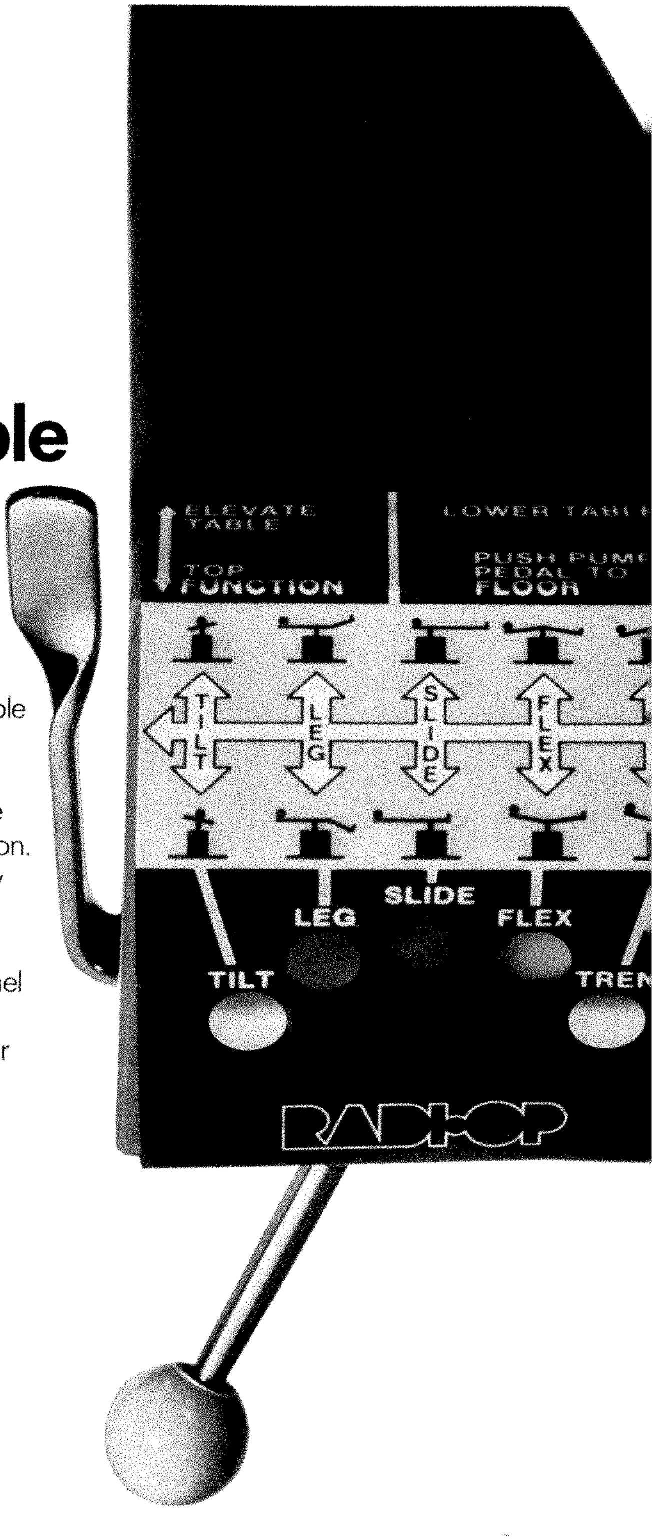
An advanced mobile surgical table with just two simple controls

Siemens Radi-op – a universal table with movable top. The single movable control arm and a simple toe-pedal operation gives complete mobility. The control arm smoothly positions the table to any of the six basic settings – quickly and with error-free selection.

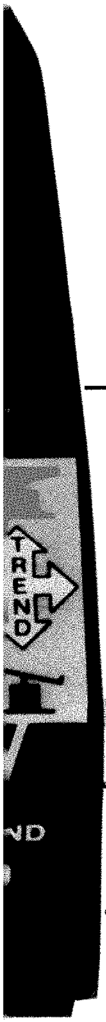
This variety of precise positions helps make any operating procedure smoother, speedier and more efficient.

Other features include a built-in cassette channel for standard radiology procedures, a completely sealed fluid drive hydraulic system and a positive floor lock system – plus a range of accessories.

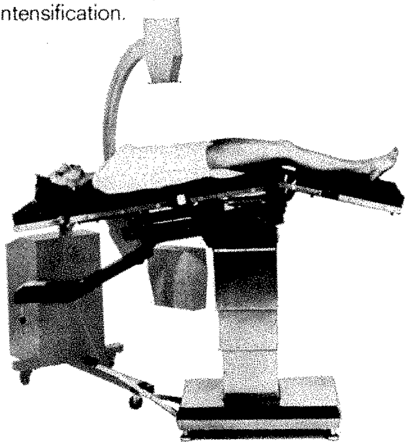
For full details write to: Siemens Limited,
Medical Group, Siemens House, Windmill Road,
Sunbury-on-Thames, Middlesex, TW16 7HS.
Tel: 09327 85691



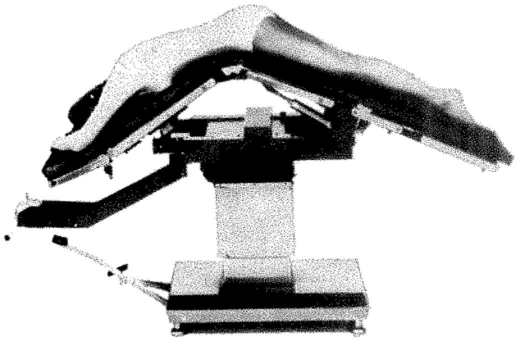
In the world of electro-medicine. Siemens has the answer



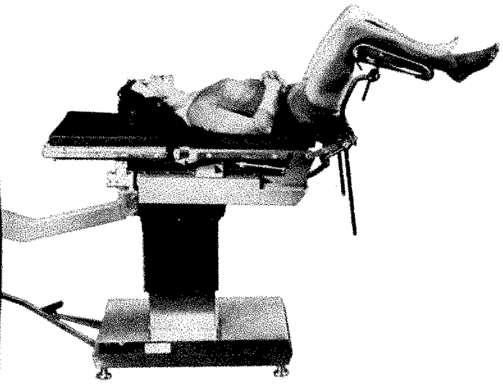
Gall Bladder. Unobstructed access above and below the table top for use with image intensification.



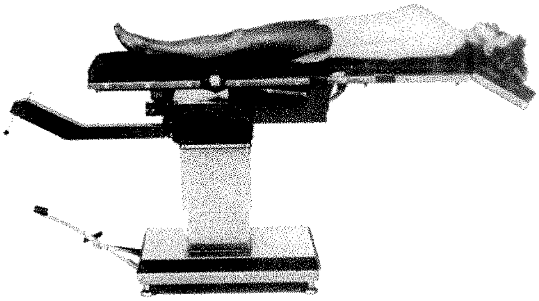
Proctology. Flex control provides smooth, effortless positioning of the patient for proctologic procedures.



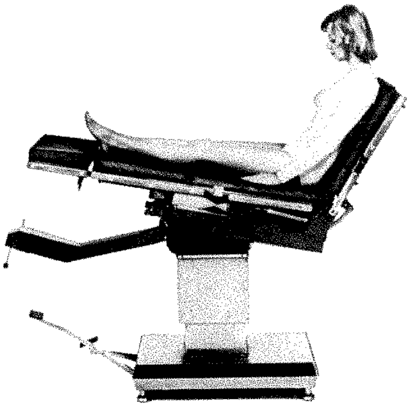
Lithotomy. The Radi-op table offers elevation of the pelvic area to provide access to the surgical site.



ENT. Total unobstructed access to the patient by the surgical team.



Neurosurgery. Unimpeded approach by the surgical team for all neurosurgical procedures performed in the sitting position.



Kidney. Optimum table flex without use of a kidney elevator for greater patient safety and comfort.

Eating patterns in patients recovering from major surgery—a study of voluntary food intake and energy balance

A. F. HACKETT, C. K. YEUNG AND G. L. HILL*

SUMMARY

Voluntary food intake (VFI) and energy balance were studied in 12 adult patients over a 2-week period following elective colectomy. Daily VFI was recorded by weighing all food presented to the patient as well as any rejected by him or her. Home VFI was estimated by a dietary history technique. Energy balance was calculated from the VFI and from the changes in body fat and protein that occurred over the study period.

The home VFI of the males was greater than that of the females with mean values of 2342 ± 542 kcal per day and 1666 ± 444 kcal per day respectively (mean ± 1 s.d.; $P<0{\cdot}05$).

Eleven patients began to eat 2–7 days after the operation, reaching a maximum VFI in stepwise fashion between 7 and 14 days. The maximum VFI reached during this period was related to the home VFI ($r = 0{\cdot}84$; $P<0{\cdot}01$). The twelfth patient required a second operation on the fifth postoperative day and began to eat 4 days later, reaching a maximum after a further 9 days.

No simple relationship was found between postoperative VFI and energy output over the study period. The higher the energy output, the more energy was derived from endogenous fat and protein. An average energy deficit of 1155 kcal per day (range +197 to −2758) was observed, and there was no significant relationship between this deficit and the VFI, which averaged 949 kcal per day (range 371–1833).

It is concluded that the amount of food consumed by post-surgical patients is dependent primarily on their previous home intake and not on their energy output. Patients with high energy outputs do not compensate by increasing VFI and large energy deficits can develop.

IN a recent study of surgical patients the average values for the various nutritional markers measured were changed in the direction of protein energy malnutrition (Hill et al., 1977). These changes were greatest in patients who had had a major surgical operation more than a week previously, many of whom had conditions which are known to increase energy output, such as sepsis or malignancy.

It is not known, however, if the magnitude of the energy deficit, i.e. the degree of malnutrition, is related to deficient food intake in the postoperative period. We therefore studied voluntary food intake (VFI) and energy balance in a group of patients recovering from a major surgical operation.

Patients and methods

Patients

Twelve patients (6 men and 6 women) admitted to the University Department of Surgery at the General Infirmary, Leeds, between September 1977 and April 1978, for elective major colorectal operations were studied. The men and women were on separate wards and only one observer (A. F. H.) was involved in assessing the VFI of all patients. Informed consent was obtained and no patient was lost to the study through lack of cooperation.

Table I shows the sex, age, preoperative body weight, diagnosis and the type of operation for each patient studied. All made an uncomplicated postoperative recovery, except for one (*Case* 3), who developed a leak from her ileorectal anastomosis on the fifth postoperative day. She underwent reoperation and an end-ileostomy was established. Her progress was then uncomplicated for the remainder of the period studied.

Home voluntary food intake

Pre-admission VFIs were assessed by a 7-day dietary history, giving an estimate of recent 'unusual consumption'. Portion size was recorded in household measures and later converted to grammes or millilitres. This record was then cross-checked against a comprehensive list of foods and weekly frequency of consumption (and portion size) was noted. The total weekly nutrient intake was divided by seven to give an arbitrary average daily intake.

Postoperative voluntary food intake

The VFI after surgery was assessed by weighing each dietary item presented to the patient and any items rejected by him or her. Drinks were assessed by volume, e.g. cupful. All patients were visited between each meal to assess any incidental intake of nutrients and such foods or duplicates were weighed whenever possible. Every effort was made to ensure that the patients studied were treated no differently from the other patients on the ward. The food intake was converted to nutrient intake using standard tables (McCance and Widdowson, 1973), and manufacturer's data where appropriate. By extrapolating from the work of Stock and Wheeler (1972), the overall error of this method for measuring VFI is approximately ±15 per cent.

Energy balance

This was calculated from the VFI and from the changes in body fat and body protein that occurred over the study period. The body tissue changes were measured using the method of Hill and his colleagues (1978). In brief, the patients were weighed and body fat was calculated from the thickness of the mid-biceps, mid-triceps and subscapular skinfolds (Durnin and Womersley, 1974). All the anthropometric measurements were made by one author (C. K. Y.). Total body nitrogen (TBN) was measured by *in vivo* neutron activation analysis and total body protein was calculated from this by multiplying by 6·25. Body weight, body fat and body protein were measured in each patient just before operation and 14·7 ± 1·8 days (range 11–16 days) after operation.

The changes in body composition were then considered in terms of their energy value, i.e. 1 g of fat = 9 kcal and 1 g of protein = 4 kcal. Energy output was then calculated according to the equation: Energy output = Energy intake (VFI) + Energy lost (loss of fat + loss of protein).

Results

Home VFI for energy was greater ($P<0{\cdot}05$) for the men (2342 ± 542 kcal) than for the women (1666 ± 444 kcal), although the average contribution of protein to the home energy intake was similar—13·3 ± 1·8 per cent for men and 13·7 ± 7·3 per cent for women.

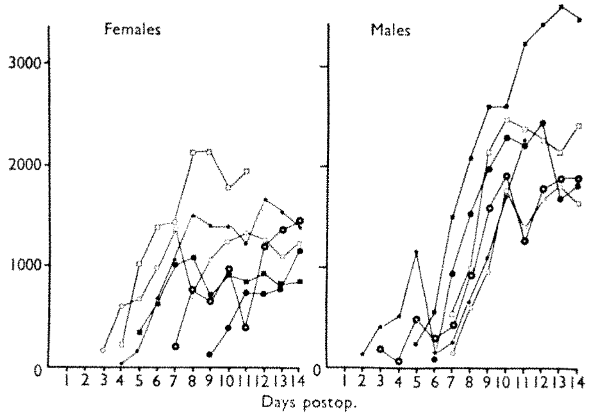

Fig. 1. Daily postoperative voluntary food intake (energy), in kilocalories per day.

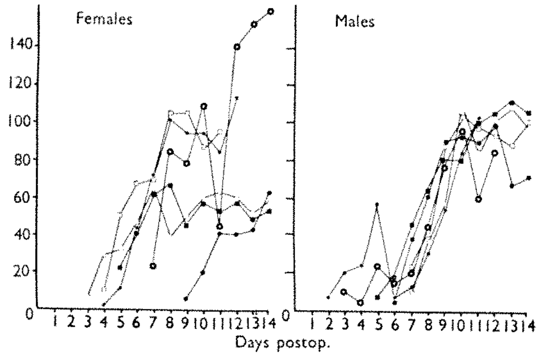

Fig. 2. Daily postoperative voluntary food intake (energy), this time expressed as a percentage of the estimated previous home voluntary food intake (energy).

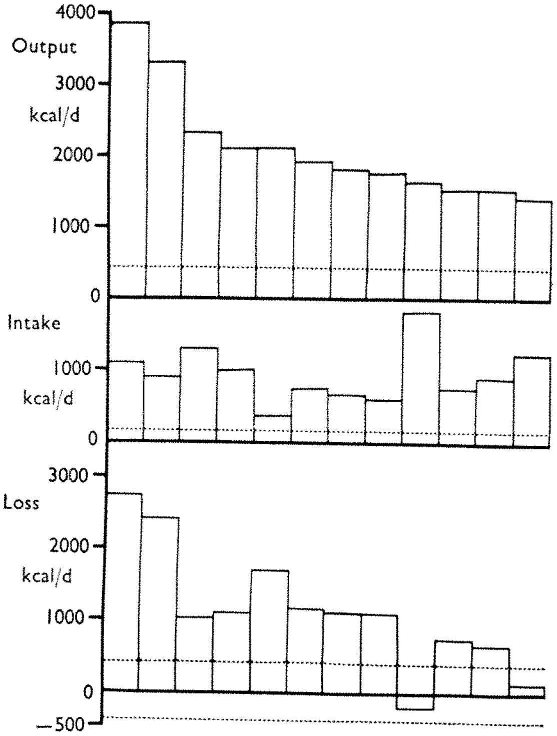

Fig. 3. Average energy balance for the period studied. The dotted lines indicate the maximum difference between the measurement, which can, with 95 per cent probability, be attributed to measurement error alone.

Home VFI was not related to body weight but there was a positive correlation with total body protein ($r = 0{\cdot}56$, $P < 0{\cdot}05$) and a negative correlation with total body fat ($r = -0{\cdot}80$, $P < 0{\cdot}01$).

Fig. 1 shows the daily postoperative VFI in terms of energy for each patient. All were in hospital for a minimum of 11 days after operation, but 7 were home by day 14. It can be seen that no patient consumed any nutrients on the first postoperative day and VFI commenced on an average of 4·7 days (range 1–9) after operation. All but one patient (*Case* 3, who had a further operation on postoperative day 5 and began eating 4 days later) were eating by day 7, the range at that time being 168–1504 kcal. Up until day 7 the intake of only 2 patients had exceeded 1000 kcal per day. By day 11 the range of VFI was 408–3218 kcal.

Fig. 2 shows the daily postoperative energy intake expressed as a percentage of the estimated home VFI. A stepwise increase in VFI occurred in most patients until the home VFI level was reached. Thereafter a strong tendency to maintain VFI at the home level was seen. Nine patients had reached their home VFI level by day 14, 1 patient (*Case* 3) reached this level on day 18 (13 days after her second operation) and the remaining 2, both females, maintained their VFIs at a level lower than their estimated home VFI.

The maximum 24-h energy intake up to postoperative day 11 was significantly correlated with the 24 h home VFI ($r = 0{\cdot}84$, $P < 0{\cdot}01$).

Fig. 3 shows the components of the average daily energy balance for each patient. It can be seen that energy intake was not related to energy output or energy lost. The average energy loss, or deficit, for the 2-week period studied was 16 176 kcal, ranging from a gain of 2950 kcal to a loss of 33 095 kcal; this approximates to an average loss of 1155 kcals per day.

Discussion

The mean home VFIs for men and women averaged only 78 per cent of the daily intake for energy recommended by the Department of Health and Social Security (1969). These standards, however, only strictly apply to populations of healthy people. Eight of our patients had lost between 6 per cent and 17 per cent of their pre-illness weight when they presented for operation. One patient with Crohn's colitis had been gaining weight prior to operation but this was probably due to the large dose of steroids which she was taking.

Most of our patients had cancer of the bowel. Weight loss in these patients is probably due to a combination of an inadequate food intake caused by factors such as anorexia, depression and abnormalities in taste sensation (DeWys and Walters, 1975) and an increased metabolic rate (Warnold et al., 1978). Although our method of estimating home VFI may be subject to systemic error, it does seem reasonable to conclude that home energy intake was inadequate to meet home energy expenditure for the majority of these patients and that it was less than the intake during health.

Home VFI was not found to be related to body weight; a finding that is in accord with the results summarized by Garrow (1974). However, a positive relationship was found with total body protein and a negative relationship with total body fat. This latter finding explains the absence of a correlation with body weight and is in keeping with the lipostatic theory of VFI control as reviewed by Andersson (1972).

Food intake, energy expenditure and balance have been measured a number of times before in surgical patients (Kinney et al., 1968). Such measurements have usually been made in a metabolic or other specialist unit. The food offered under these conditions is often very different in quantity and quality from that which the average ward patient receives. Nursing and medical attention, which are probably different on such units, may also influence VFI.

In the present study we have described the postoperative voluntary food intake of patients recovering from major colorectal operations in an ordinary ward. Food intake effectively ceases for approximately 5 days after this sort of surgery and then rises stepwise over 4–11 days to reach a maximum similar to the previous home VFI. In this way a considerable energy deficit is built up.

This study shows that energy intake in the early postoperative period was decided by habit and not by requirement (energy output). The overeating to 'repay' an energy deficit ('in a few days') observed by Adam and his colleagues (1957) in healthy active soldiers was not observed in these hospitalized patients over the period studied. Although the range of home VFIs was large (903–3268 kcal) and the food consumed in hospital was frequently different from that consumed at home, the patients were usually able to reach home levels of intake during the second postoperative week. This suggests that they were able to detect and regulate their energy intake on a relatively short term basis. Two female patients did not reach their estimated home VFI. For one there is some retrospective evidence of the home VFI being originally overestimated. The other was an 81-year-old woman who was a little vague about her eating habits. One female greatly exceeded her estimated home VFI, but she also had the lowest home VFI.

There were several complaints about the quality of the hospital food, and generally patients refused to eat much of the food offered to them (especially the women). The quality of the food, however, would not seem to be of much importance in determining postoperative hospital food intake. Conversely, the VFI may determine the patient's opinion of the food. Many patients apologized for leaving food and had to be reassured in order to protect the study. Generally the patients' evaluation of their food intake was found to be a very unreliable guide to what they actually ate.

We saw very few serious or effective attempts by the nursing staff (whose evaluation of VFI was often as poor as the patients) to improve the food intake of those patients consistently rejecting food.

The energy balance data showed that the patients with the greatest need for energy, i.e. those with the highest energy output, had proportionately least chance of meeting this need from VFI. Intake appeared unable to respond to the energy output over the 2-week postoperative period studied. In this way an appreciable energy deficit was created (range +197 to −2758 kcal per day) in most patients.

The calculated postoperative energy outputs for these patients are of the same magnitude as those reported by others (average 2102 kcal per day, range 1401–3850). Kinney et al. (1968) studied the energy balance of 10 major surgical cases. In their study the postoperative energy output, calculated from the estimated protein and fat losses, averaged 1498 kcal per day (range 1205–1798). The measured resting metabolic expenditure averaged 1396 kcal per day (range 1209–1663) and the energy intake averaged 884 kcal per day (range 451–1254). In the present study energy intake averaged 949 kcal per day (range 371–1833). Thus, the data from these two studies would seem to be quite comparable, although our patients had slightly higher energy outputs, which might reflect the extra exercise that is possible on a general ward, or more probably the increased magnitude of the surgical procedure undergone by our patients.

Our most important point is that the amount of food consumed by patients recovering from colorectal operations is dependent primarily on their previous home intake and not on their energy output. Patients with high energy outputs after major operations do not appear to be able to compensate by increasing food intake.

This work helps to explain how some patients with high energy expenditures develop protein energy malnutrition while recovering from major surgical procedures.

A simple suction device for removing foreign bodies in the rectum

KENNETH STEVEN, JØRGEN LYKKE AND THOMAS STEENBERG HANSEN, *Department of Surgery K, Frederiksberg Hospital, Copenhagen, Denmark.*

WE describe here a simple, easily made suction device that has proved efficient for removing foreign bodies lodged in the rectum.

The device consists of two parts: a de Pezzer 34F-gauge catheter and an ordinary suction tubing set. The tip of the de Pezzer catheter is cut off, and the plastic end of the suction tubing set is inserted all the way through the de Pezzer catheter. The tubing fits tightly within the de Pezzer catheter, the cut end of which thus functions as a suction disc.

For use, the device is placed in contact with the foreign body in the rectum and suction is applied with a standard theatre sucker. After waiting for a few seconds to allow the pressure in the device to decrease, traction is applied to the de Pezzer catheter. Suction of about 600 mmHg—capable of lifting a full litre-bottle of saline by its base—can be obtained with an ordinary theatre sucker.

The device functions in an atraumatic manner because the diameter of the device is usually smaller than that of the foreign body. We have found this method to be of value, even for removing objects such as a bottle lodged in the rectum.

The Celestin tube in the palliation of carcinoma of the oesophagus and cardia

N. R. SAUNDERS*

SUMMARY

A series of 105 patients with dysphagia due to inoperable carcinoma of the oesophagus or cardia of the stomach, and 11 patients with dysphagia secondary to malignant mediastinal nodes, was treated by intubation with a Celestin tube. The hospital mortality was high but 81 patients left hospital and 29 were still alive at 6 months. The prognosis for those with dysphagia due to malignant posterior mediastinal nodes was very poor, with no survivors at 6 months. Oesophageal perforation was a serious operative complication, with a hospital mortality of 83 per cent. Chest and wound infections were the most common postoperative complications occurring in 28 and 20 per cent of the patients, respectively.

The restoration of swallowing was satisfactory in the majority of survivors although readmission with a blocked or displaced tube was not uncommon.

ALTHOUGH it is generally accepted that primary carcinomas of the lower oesophagus and cardia of the stomach are best treated by resection, 65 per cent of patients are inoperable at the time of their first consultation (Miller, 1962). Palliative procedures to relieve dysphagia are, therefore, of considerable importance and ideally these procedures should be both safe and simple. Bypass procedures have been tried by a number of authors (Allison and Borrie, 1949; Miller, 1962; Barnard et al., 1966; El Domeiri et al., 1970; Postlethwaite et al., 1971; Stephens, 1971), but the mortality from these operations may reach 60 per cent and the palliation is often unsatisfactory. Better results have been achieved by intubation of the malignant stricture, as first suggested by Leroy d'Etiolles of France in 1845 (Celestin, 1959). The first successful intubation was reported by Sir Charles Symonds in 1887, and since that time many different tubes have been used. In 1924 Souttar introduced a tube made of German silver wire with an expanded top which could be inserted via the oesophagoscope (Souttar, 1924, 1927). The next significant advance came in 1956 when Mousseau and Barbin introduced a neoplex tube which was inserted by a 'pullthrough' technique through a high gastrotomy (Mousseau et al., 1956) and then in 1959 Celestin introduced his modification of the Mousseau–Barbin tube. This had barrel-shaped proximal flange and a detachable pilot bougie of solid polythene. This tube is now widely used for palliative intubation of oesophageal neoplasms and a review of its use over a 10-year period is presented.

Patients and methods

Patients

Over a 10-year period (December 1967–October 1977) 105 patients (71 male, 34 female) with dysphagia secondary to carcinoma of the oesophagus or cardia, and 11 patients (10 male, 1 female) with dysphagia secondary to extrinsic compression of the oesophagus by malignant mediastinal nodes, were treated by intubation with a Celestin tube. The average duration of dysphagia before the first medical consultation was 6·4 months, but 1 patient waited 3 years before seeking treatment.

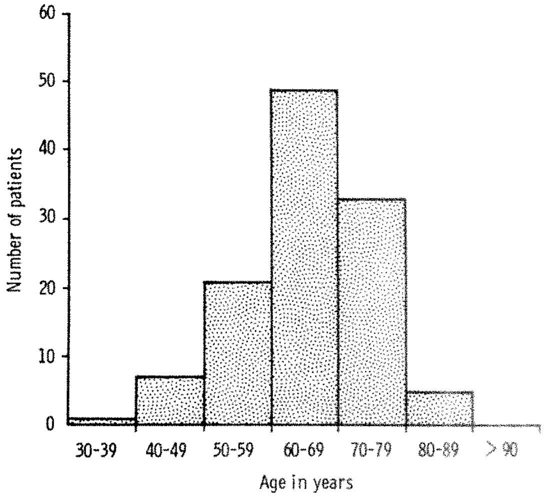

Fig. 1. Age distribution of patients in the series.

The average age was 65 years with a range of 37–86 (*Fig.* 1).

The site of the lesion was accurately defined in all cases and those with lesions arising at the oesophagogastric junction were classified as lower oesophageal (squamous) or cardiac (adenocarcinoma) depending on the histology. Twenty patients had lesions of the middle third of the oesophagus, 53 had lesions of the lower third and 28 had lesions of the cardia of the stomach. Four patients (3 male and 1 female) who had previously undergone oesophagogastrectomy for their malignancy developed dysphagia secondary to a recurrence at the anastomotic site and required Celestin tube intubation. Histological confirmation of the diagnosis was obtained in all cases.

The 11 patients with dysphagia secondary to extrinsic pressure on the oesophagus all had carcinoma of the bronchus with metastatic involvement of the posterior mediastinal nodes.

There were 2 cases of malignant tracheo-oesophageal fistula.

Technique

All patients underwent preliminary oesophagoscopy and biopsy. In 24 patients (21 per cent) the oesophageal tumour was considered operable on clinical, radiological and endoscopic grounds and inoperability was only established after exploratory thoracotomy in 18 patients and thoraco-abdominal exploration in 6.

In the remaining 92 patients (79 per cent) either inoperability was established at exploratory laparotomy or resection of the tumour was precluded due to advanced age or poor general health of the patient or the presence of distant metastases.

For those patients who underwent laparotomy by a left upper paramedian or upper midline incision, the Celestin tube was inserted as described by Celestin (1959) using a pullthrough technique and high gastrotomy. Tension sutures were used routinely in the closure of the abdominal wound.

In those who underwent thoracotomy alone a radial or circumferential incision in the diaphragm was made to gain access to the stomach for fixation of the distal end of the tube.

Table I: MORTALITY

Time after intubation (mth)	No. deceased	%
1	39	34
3	62	53
6	87	75
9	100	86
12	108	93
15	114	98

Table II: MORBIDITY

Complication	No. of patients	%
Bronchopneumonia	33	28·4
Wound infection	23	19·8
Perforated oesophagus	12	10·3
Empyema	8	6·9
Blocked tube	4	3·4
Displaced tube	3	2·6
Intestinal obstruction	3	2·6
Subphrenic abscess	2	1·7
Gastric fistula	2	1·7

Dilatation of the malignant stricture was required in a number of patients before intubation with the Celestin tube.

Results

The 116 patients in this series were mostly elderly and many were debilitated as a result of the dysphagia and advanced malignancy. They thus represented a group of patients with an increased risk of both surgical and anaesthetic complications.

Mortality

Twenty-one patients (18 per cent) died within 7 days of operation including both patients with tracheo-oesophageal fistulas. The hospital mortality for the group was 30 per cent and the 3-month mortality, 53 per cent (*Table I*). Twenty-nine patients survived for longer than 6 months and achieved reasonable palliation, and the longest survivor died 28 months after insertion of his tube.

The prognosis for those patients with dysphagia secondary to posterior mediastinal deposits was worse than for those with dysphagia secondary to carcinoma of the oesophagus or cardia. The hospital mortality in the former group was 45 per cent and there were no survivors at 6 months.

The commonest causes of death were bronchopneumonia and metastatic spread of tumour.

Morbidity (*Table II*)

Bronchopneumonia was the commonest postoperative complication, occurring in 28 per cent of patients.

The relatively high incidence of wound infection—20 per cent of patients—was probably related to the difficulty in maintaining a sterile operative field during insertion of the tube. Most infections were superficial, and there were no cases of complete wound disruption in the series. The routine use of tension sutures in abdominal wound closure is believed to be an important factor in preventing this serious complication.

The oesophagus was perforated at the time of intubation in 12 patients (10 per cent) and in 8 of these subsequent drainage of an empyema was necessary. Only 2 of these patients left hospital and both died within 2 months. The mean survival of the remaining 10 patients in this group was 13 days.

In 3 cases the Celestin tube became displaced in the postoperative period and repositioning was necessary to prevent recurrent dysphagia; and in 4 patients the tube became blocked within 14 days of insertion and required clearing endoscopically.

The mean length of hospital admission was 19 days and those patients who left hospital achieved satisfactory palliation. They were able to swallow liquids and a semi-solid diet but tube blockage was a common cause of readmission. Twelve patients were readmitted once with a blocked tube and 4 patients had two or more readmissions. Reflux did not appear to be a major problem.

Late displacement of the Celestin tube was an uncommon complication, but when it did occur reoperation was normally necessary. In this series 11 patients (8 per cent) required reoperation for blocked or displaced tubes.

Discussion

The overall 5-year survival rate from malignant oesophageal obstruction varies from 1 to 9 per cent depending on the series quoted (Gunnlaugsson et al., 1970; Leon et al., 1971; Hankins et al., 1972). These poor figures are, in part, related to the fact that in most series two-thirds of the patients are inoperable when first seen. It is against this background that the survival figures of any palliative procedures must be measured.

Carcinoma of the oesophagus makes up 2 per cent of all malignant tumours and since 91 per cent of patients with this disease develop dysphagia (Parker et al., 1952), safe and simple procedures to restore swallowing are of considerable importance.

Various authors report operative mortalities of 10–28 per cent for oesophageal intubation by the pull-through technique and the 18 per cent operative mortality of this series is within that range. These figures compare favourably with those for various bypass procedures and palliative resections, in which the operative mortality is generally higher (10–60 per cent) and the palliation achieved often unsatisfactory (Allison and Borrie, 1949; Barnard et al., 1966; El Domeiri et al., 1970; Postlethwaite et al., 1971; Stephens, 1971).

In 1968 Plested et al. reviewed 12 000 reported cases of malignant oesophageal obstruction and found that 85 per cent died within 1 year regardless of therapy. With this prognosis it is important that restoration of swallowing is achieved quickly and simply and the patient's hospital admission kept to a minimum. In this series 81 patients (70 per cent) left hospital, having spent on average 19 days as inpatients. Of these, 29 patients (42 per cent) were still alive at 6 months and were without significant dysphagia, thus confirming successful palliation in this group.

When intubation is used to palliate dysphagia due to metastatic deposits in mediastinal nodes, the prognosis is very poor (Provan, 1969), with a hospital mortality of 45 per cent. However, in our series of 11 patients, 6 left hospital following intubation and 2 survived for 5 months, indicating that reasonable palliation can be achieved in this group also.

The insertion of a Celestin tube by the pullthrough technique involves a laparotomy and gastrotomy and these manoeuvres contribute significantly to the high hospital mortality and morbidity associated with the procedure. Recently the technique of fibreoptic endoscopic palliative intubation of oesophagogastric neoplasms with a Celestin tube has been reported (Atkinson and Ferguson, 1977). This procedure, which avoids a laparotomy, is associated with a reduction in morbidity and hospital mortality and a shorter hospital admission than the conventional pullthrough technique, although the long term outlook remains unaltered. Whichever method of intubation is used, a significant proportion of patients achieves reasonable palliation in terms of increased length and quality of survival.

The role of thrombolytic therapy in the management of phlegmasia caerulea dolens

M. S. ELLIOT, E. J. IMMELMAN, P. JEFFERY, S. R. BENATAR, M. R. FUNSTON,
J. A. SMITH, P. JACOBS, B. J. SHEPSTONE, A. D. FERGUSON AND J. H. LOUW*

SUMMARY

Two cases of phlegmasia caerulea dolens with peripheral venous gangrene treated with streptokinase are presented. Both patients had excellent results, beyond expectation. The literature is reviewed and the symptomatology, aetiology, pathogenesis and current thoughts on treatment are discussed.

PHLEGMASIA caerulea dolens is a rare, but potentially lethal, form of venous thrombotic disease. It is reversible, but may result in gangrene, pulmonary embolism or even death. Other terms describing the same entity include blue phlebitis ('la phlebité bleu de Grégoire') or acute massive venous thrombosis. The most severe form of this disease is venous gangrene. Haimovici (1966) groups phlegmasia caerulea dolens and venous gangrene under the heading of 'ischaemic thrombophlebitis', as the dominant manifestation is tissue ischaemia. In caerulea dolens the ischaemic changes are reversible as opposed to those of venous gangrene. The basic pathological condition in caerulea dolens is near total venous thrombotic occlusion, whereas in venous gangrene, there is total occlusion. In spite of being recognized for some 400 years, caerulea dolens still has a mortality of approximately 25 per cent and an amputation incidence of 50 per cent. Treatment has evolved from conservative medical management to venous thrombectomy, which has produced some improvement in immediate results. Since 1970 several reports (Paquet et al., 1970; Tsapogas et al., 1973; Roberts, 1976) have shown excellent results after treatment of caerulea dolens with streptokinase. In view of this and also because of the known poor long term results after thrombectomy (Lansing and Davis, 1968; Johansson et al., 1973), we used streptokinase in the treatment of 2 recent cases of caerulea dolens with venous gangrene, with extremely satisfactory results.

Case reports

Case 1: A 43-year-old female developed an iliofemoral thrombosis in her left leg. She was treated with heparin for 7 days and then given warfarin. On the third day of warfarin therapy, when the prothrombin index was 36 per cent, she developed severe pain in her left leg, which was uncontrolled even with heavy doses of morphine. Eight hours later the forefoot was cold and blue. A tentative diagnosis of an acute arterial occlusion was made and she was transferred to Groote Schuur Hospital. On arrival her temperature was 38·5 °C, respiration 38/min, pulse 148/min and her blood pressure was 140/80 mmHg. Local examination revealed the left leg to be grossly swollen to above the inguinal ligament and the lower leg mottled and blue. The distal left foot was blue-black and anaesthetic (*Fig.* 1). No movement was possible at either the ankle or the knee joint due to the oedema and extreme pain. No pulses could be detected in this limb, but Doppler examination revealed that all were audible, though diminished.

A diagnosis of massive venous occlusion with peripheral venous gangrene was made. The leg was elevated, intravenous penicillin given and streptokinase (Kabikinase, AB Kabi, Stockholm) therapy commenced using the manufacturer's recommended dosage. Within 24 h the patient's general and local condition had improved markedly (temperature 36·5 °C, pulse 90/min, respiration 22/min). The swelling was significantly reduced and all pulses were palpable (*Fig.* 2).

Haematological assessment at this time revealed satisfactory thrombolysis—fibrinogen 18 mg/100 ml, fibrin degradation products 320>640 μg/ml, thrombin time 23 s (control 10 s). Streptokinase therapy was continued for 72 h and the patient was then treated with heparin intravenously for a further 14 days. A venogram was then performed which showed occlusion of the iliofemoral system and warfarin sodium therapy was commenced shortly afterwards. The first and second toes were later amputated and a secondary closure performed. Six months later the leg appeared normal, with no evidence of oedema.

Case 2: An 18-year-old female in the 36th week of her pregnancy presented with a 12-day history of a left iliofemoral venous thrombosis. A bilateral venogram was performed which showed occlusive iliofemoral clot on the left. The patient was heparinized (10 000 units intravenously 6-hourly) and the clotting times were carefully controlled. Following delivery 12 days later, warfarin sodium therapy was commenced.

Six days later, the patient complained of severe pain in the left leg. On examination the leg was grossly swollen to above the inguinal ligament. No pulses were palpable below the left femoral. The three medial toes showed evidence of severe ischaemia and were anaesthetic (*Fig.* 3). A diagnosis of phlegmasia caerulea dolens with peripheral venous gangrene was made. (The prothrombin index at the time was 46 per cent.)

The leg was elevated, intravenous penicillin given and streptokinase therapy commenced. Twenty-four hours later the leg had improved markedly (*Fig.* 4), with only the first toe now being anaesthetic. Haematological assessment at the time showed evidence of satisfactory thrombolysis and the treatment was continued as in *Case* 1. A venogram was performed after 2 weeks which showed thrombosis of the deep venous system. Shortly afterwards the first toe and distal phalanx of the second toe were amputated. Three months later the patient had minimal oedema which was completely controlled using TED anti-embolism stockings (Kendall Company, Hospital Products).

Discussion

Massive oedema, cyanosis, excruciating pain, shock and the absence of peripheral pulses are all classic manifestations of phlegmasia caerulea dolens. This condition may occur at any age, but is commonest in the sixth decade. The two sexes are equally affected and the left lower limb is involved almost three times as often as the right. The upper limb is affected in about 5 per cent of cases.

It is clear from the literature that this condition almost always develops as a complication of another disorder. In approximately half the cases the primary pathology is carcinoma or inflammatory conditions or cardiac disease. The malignancies appear to be mainly localized to the gastrointestinal tract, whilst the inflammations appear to be equally distributed

between the respiratory and alimentary systems. The postpartum (Moore and Scott, 1956) and postoperative states (Stallworth et al., 1965) precede the development of caerulea dolens in approximately 30 per cent of cases. In 60 per cent of cases the symptoms of caerulea dolens are preceded by the more common form of venous thrombosis, phlegmasia alba dolens (Haimovici, 1966). The time lapse appears to vary from a few days to several weeks.

Past treatment of this condition has included heparin (Anlyan and Hart, 1957), sympathetic blockade (Martin, 1953), rapid passive exercise (Veal et al., 1951) and fasciotomy (Cywes and Louw, 1962).

Thrombectomy was first used in the treatment of phlegmasia caerulea dolens by Leriche in 1939. Since this time many reports of this treatment have been published (Haller, 1961; Fogarty et al., 1963). It is apparent, however, that if a satisfactory result is to be achieved, the peripheral venous capillary system must be only partly involved (Brockman and Vasko, 1965). Haimovici (1966) later confirmed this and showed that the results of thrombectomy, once peripheral gangrene had developed, were unimpressive. It is universally agreed that in caerulea dolens, thrombectomy requires a general anaesthetic and may require wide exposure of the femoroiliocaval system. Therefore, this procedure cannot be considered in the desperately ill patient, which is all too frequently the case. Reports indicate that failures occur as often as successes. The failures appear to be due to rethrombosis and pulmonary embolism, but above all to an inability to remove thrombus from the tributary veins. Even if the thrombectomy is successful, one knows from Lansing and Davis (1968) and Johannson et al. (1973) that the patient will almost certainly develop post-phlebitic sequelae.

The first report of caerulea dolens treated successfully with streptokinase was published by Paquet et al. in 1970. They described 10 cases, of which 9 had excellent results. There was no incidence of pulmonary embolism, gangrene or death. Tsapogas et al. (1973) and Roberts (1976) later described single cases treated with streptokinase, again with excellent results.

Fibrinolytic therapy offers two important advantages over surgery: it will dissolve the multiple peripheral thrombi inaccessible to thrombectomy and no anaesthesia is necessary. It must be accepted that neither thrombectomy nor streptokinase is suitable for treating ageing, adherent thrombus. In the 2 cases we have reported, the lengths of history of iliofemoral thrombosis were 10 and 30 days respectively. It was felt that in both cases surgery would be unsuccessful owing to the adherence of the thrombus lying in the main venous channels. At the same time it was obvious that the peripheral skin infarction was of a short duration and therefore that thrombosis in the tributary veins might be amenable to fibrinolytic therapy.

In conclusion, we have confirmed that phlegmasia caerulea dolens can be successfully treated with streptokinase. We would stress that in order to avoid the bleeding complications of thrombolytic therapy, this drug should not be used within 10 days of major surgery, or even longer after vascular, neurosurgical or eye operations. Its use should be restricted to the hospital environment as it requires expertise and careful attention to the mode of administration.

Acknowledgements

These two cases form part of a larger study, funding of which from the South African Medical Research Council, University of Cape Town Staff Research Grants, the Nellie Atkinson Bequest and the Harry Crossley Foundation is gratefully acknowledged.

We wish to thank the Department of Medical Illustrations for the photography and AB Kabi, Stockholm, Sweden, who kindly paid for the colour illustrations.

KABIKINASE®

(pure streptokinase)

the right answer to existing thrombi

Kabikinase is now used internationally as a more effective method of treating deep vein thrombi, pulmonary emboli and arterial occlusions. Surgical clearance is frequently both hazardous and inconvenient and reported morbidity rates are as high as 60%. Heparin and other anti-coagulants can prevent further clot formation but have no effect on existing thrombi. Kabikinase rapidly potentiates the body's own ability to dissolve blood clots.

Anaerobic Bacteria

"... the major cause of sepsis after surgery of the gastrointestinal tract or female genital tract".

Br.Med.J. **i**, 318, 1976

NOW

FLAGYL

METRONIDAZOLE

INJECTION

FOR INTRAVENOUS INFUSION

proves decisive in anaerobic infections

Only with recent improvements in bacterial culturing techniques has the pathogenic role of anaerobes in post-surgical infections been fully recognized.[1-3] Now 'Flagyl' Injection offers you a decisive means of treating these infections – which are often life-threatening and often resistant to established antimicrobials. The response to 'Flagyl' Injection is rapid and dependable,[2] as it is consistently bactericidal to pathogenic anaerobes at tissue concentrations easily achieved in treatment. Bacterial resistance is not a problem,[2,4] and 'Flagyl' is highly acceptable – as eighteen years of use in other indications has established.

Dosage: Treatment: adults and children over 12 years: 100 ml by intravenous infusion eight-hourly, administered 5 ml per minute. Oral medication with 400 mg three times daily should be substituted as soon as this becomes feasible. Treatment for seven days should be satisfactory in most cases. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 7.5 mg per kg bodyweight. Prevention: adults and children over 12 years: 100 ml by intravenous infusion immediately before, during or after operation, followed by the same dose eight-hourly until oral medication (200 to 400 mg three times daily) can be given to complete a seven day course. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 3.7 to 7.5 mg per kg bodyweight. Precautions: pregnancy; lactation; clinical and biological surveillance if recommended duration of treatment exceeded; dosage may be halved for patients with renal failure; avoid alcohol; if 'Flagyl' is to be given to patients receiving oral anticoagulants the dosages of the latter should be recalibrated. Side effects and adverse reactions: occasionally an unpleasant taste, furred tongue, nausea, vomiting (very rarely), gastro-intestinal disturbance. Drowsiness, dizziness, headache, ataxia, skin rashes, pruritus, inco-ordination of movement, darkening of the urine very rarely. During intensive and/or prolonged therapy, peripheral neuropathy has been reported. A moderate leucopenia has been reported but the white cell count has always returned to normal before or after treatment has been completed. Transient epileptiform seizures in a few patients undergoing intensive, high-dosage metronidazole radiosensitization therapy.

Intrarectal metronidazole in the prevention of anaerobic infections after emergency appendicectomy: a controlled clinical trial

J. RODGERS, D. ROSS, W. MCNAUGHT AND G. GILLESPIE*

SUMMARY
A series of 102 patients with presumptive acute appendicitis entered a prospective, randomized, clinical trial of intrarectal metronidazole given over a 48-h period commencing before surgery. Adequate levels of circulating metronidazole were achieved. A significant reduction in the incidence of anaerobic wound infection was observed in the treated group ($P<0{\cdot}02$). The convenience and short duration of the prophylactic regimen allowed early discharge from hospital. No untoward effects were observed.

THE success of prophylactic metronidazole in controlling serious wound infection due to Gram-negative anaerobic organisms after elective colonic surgery has already been established (Goldring et al., 1975; Willis et al., 1977), although the importance of simultaneous administration of an antimicrobial agent to control organisms of the coliform group remains uncertain. In acute appendicitis, Willis et al. (1976) have extended this prophylactic antimicrobial approach to emergency surgery, using metronidazole alone over 8 days, commencing just before surgery.

The aim of the present study was to examine further this prophylactic approach and to assess the efficacy of short term metronidazole, given solely as suppositories, in preventing anaerobic wound infection after appendicectomy for acute appendicitis.

Patients and methods

A consecutive series of 102 patients in whom a presumptive diagnosis of acute appendicitis had been made entered the trial. Patients were randomly allocated to receive identically marked suppositories containing either metronidazole 1 g or placebo (Witepsol). The first suppository was inserted at the time of presumptive diagnosis and thereafter a further suppository was inserted 8-hourly for 2 days. Proctoscopy was performed within 24 h of completing the course in the first 41 patients in the series.

Blood metronidazole levels

A venous blood sample was taken at the time of induction of general anaesthesia to measure the circulating level of metronidazole and the time interval between insertion of the initial suppository and blood sampling was noted.

Bacteriology specimens

The following specimens were taken for culture at the time of surgery: (*a*) a swab of peritoneal fluid; (*b*) a swab from the serosal aspect of the appendix; (*c*) after removal of the appendix and wound closure, the appendix was opened in its distal third and a swab of luminal content taken. All swabs were immediately immersed in Stuart's transport medium for transfer to the laboratory. Cultures were incubated both aerobically and anaerobically with 10 per cent added carbon dioxide for at least 48 h. The following culture media were used: 6 per cent horse blood agar, 6 per cent horse blood agar incorporating gentamicin sulphate 15 μg/ml, MacConkey's agar and Robertson's cooked meat broth. Bacteria were identified by standard procedures (Cowan and Steel, 1974).

Pathology

In all cases the appendix was subjected to routine histopathological examination.

Wound inspection

Formal wound inspection was made on the third or fourth day and again on the tenth day; in all cases where early ward discharge had been allowed arrangements were made for wound inspection on the tenth postoperative day. For the purposes of this study 'wound infection' was defined as the presence of pus or a purulent exudate at the wound.

Exclusions

Twelve patients were withdrawn from the study, 4 because of an error in the diagnosis at operation (1 acute cholecystitis, 1 caecal diverticulitis, 1 inflamed Meckel's diverticulum and 1 already established appendix abscess). Six patients were excluded because they had received antibiotics (intra- or postoperatively); in 5 of these cases the surgeon had been unwilling to leave his patients in a double-blind situation and in the sixth case preoperative administration of an antibiotic before hospital admission was discovered. Two patients were excluded because they were given the wrong suppositories. Thus 90 patients remained in the study.

Results

Matching of the groups (*Table I*)

Comparison of the groups with regard to age and sex showed no significant differences. In this study we classified appendices as normal, inflamed or gangrenous/ruptured. Unlike the earlier study of Willis et al. (1976) we have not recognized lymphoid hyperplasia as a significant pathological entity and have included such appendices in our normal group. Eighty-four per cent of appendices in our series were significantly inflamed. While there was no significant difference between the incidence of inflamed and gangrenous/ruptured appendices in the placebo and metronidazole groups, there were significantly fewer normal appendices in the metronidazole group compared with the placebo group and in this respect there was a slight bias against the metronidazole group (*Table I*). The relative incidence of acute appendicitis in the under-13-year-olds is greater than our figures suggest since most younger children from our area are admitted to a paediatric hospital. The anatomical sites of the appendix at operation were similar in both groups.

Blood metronidazole levels at the time of surgery

For 36 of the 42 patients who received metronidazole, the time interval between insertion of the first suppository and induction of anaesthesia was recorded and this is plotted against the circulating level of metronidazole in *Fig*. 1. At commencement of surgery following the initial single suppository, the mean

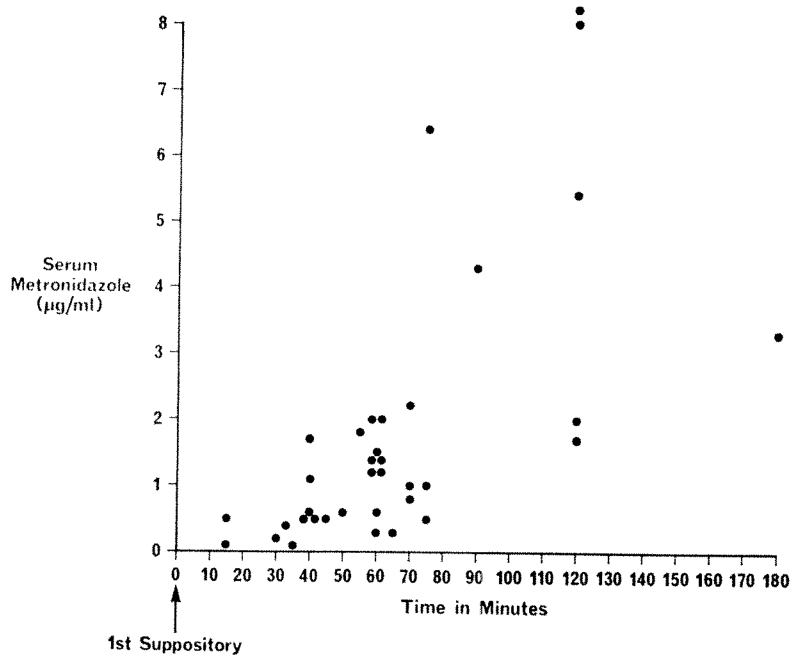

Fig. 1. Levels of circulating metronidazole at the time of surgery after a single 1-g suppository.

Table I: COMPARISON OF GROUPS

	Metronidazole (n = 42)	Placebo (n = 48)
Male/Female	27/15	27/21
Age		
<13	6	8
13–24	26	27
25–50	7	12
>50	3	1
Pathology		
Normal	2*	12*
Inflamed	30	31
Gangrenous ruptured	10	5

* There are significantly fewer normal appendices in the metronidazole group ($P<0{\cdot}0066$, Fisher's exact test). No other significant differences exist between the groups. The overall incidence of normal appendices in the series was 16 per cent; inflamed appendices 67 per cent; ruptured/gangrenous appendices 17 per cent.

Table II: BACTERIOLOGY

	Metronidazole		Placebo	
	Anaerobes		Anaerobes	
Site	Present	Absent	Present	Absent
Peritoneal fluid	2	40	2	46
Appendix serosa	10	32	13	35
Appendix lumen*	32	8	43	5
Operation wound	0	42	7	41

* Luminal swabs were not obtained in 2 patients.
In every case one or more strain of bacteroides comprised the anaerobic flora. Two instances of purely aerobic wound infection occurred (*see* text).

blood metronidazole level was 1·8 mg/l and the range was 0·1–8·2 mg/l. This indicated that satisfactory absorption from rectal mucosa was taking place, despite the short interval between insertion of the first suppository and sampling of blood. The mean time interval from insertion of the initial suppository to surgery was 64 min. From *Fig.* 1 it is evident that higher blood levels can be attained when this time is longer.

Bacteriology (*Table II*)
The presence of organisms in the peritoneal cavity, serosa of the appendix or indeed the lumen of the appendix gave little indication as to whether wound infection was likely to occur. Likewise, the presence or absence of turbid or clear peritioneal fluid was a poor guide to the development of an infected wound.

Wound infection
Seven of the 48 patients in the control group had severe anaerobic wound infection. In 5 of these patients a cellulitis developed which spread into the flank. In 3 this was associated with marked postoperative paralytic ileus and abscess formation requiring surgical drainage. In all 7 cases pus from the wound yielded bacteroides and in all instances the organisms were present in the lumen of the appendix. All 7 wounds yielded coexisting coliform organisms (*Escherichia coli* 6; *Klebsiella aerogenes* 1). Blood cultures were negative. All cases responded to a course of intramuscular gentamicin and lincomycin. The minimum inpatient stay was 18 days.

By contrast, there was no instance of anaerobic wound infection in the group that received metronidazole suppositories and this advantage for patients in the treated group is statistically significant ($P<0{\cdot}02$, Fisher's exact test).

There were 2 patients in the series who had aerobic wound infection, both in the metronidazole group. (One severe wound infection due to *Staphylococcus aureus* resulted in a 2½ week stay in hospital.) One of these cases was a patient who developed a stitch abscess on the tenth day having been discharged on the third postoperative day with an initially satisfactory wound. One millilitre of pus was aspirated from the wound and this yielded a non-haemolytic streptococcus.

The use of peritoneal drains

Twelve patients in the series had peritoneal drains brought out through a separate stab wound. The usual indication for drainage was the finding of purulent peritoneal exudate and/or a gangrenous or ruptured appendix. Of the 12 patients, 4 had received placebo (3 of whom developed wound infection) and 8 had received metronidazole (none developed infection).

Exclusions

Of the 12 patients excluded from the study, 5 were withdrawn from the trial by the surgeon at the time of operation after administration of the initial preoperative suppository (metronidazole, 2; placebo, 3). All 5 had ruptured appendices, all had separate stab wound drains and received parenteral gentamicin and lincomycin for at least 3 days. Wound infection occurred in 2 of these cases (placebo and metronidazole one each) and in both cases culture yielded coliforms and bacteroides.

Proctoscopy

Forty-one patients (19 placebo; 22 metronidazole) had proctoscopy performed after completing the course of suppositories. No patient showed any abnormality. No practical difficulties arose in the administration of suppositories in the early postoperative period.

Discussion

This study of emergency appendicectomies clearly shows the ability of metronidazole to prevent wound infection from endogenous anaerobic bowel microflora. Use of the intrarectal route to administer the drug is safe and convenient and has clear advantages in the preoperative and immediate postoperative situation where the oral route is not always feasible and where intravenous administration would be unnecessary. Our results confirm that metronidazole is rapidly and satisfactorily absorbed via the rectal mucosa and that therapeutic blood levels can be attained even when there is only a short time interval between insertion of the first suppository and commencement of the operation. Willis et al. (1976) have had similar success using metronidazole suppositories as part of an 8-day course of therapy. In the light of our results, this longer course involving postoperative oral administration would appear to be unnecessary provided that the patient receives protective antimicrobial therapy during the peroperative period, i.e. the period during which surgery is exposing tissues to contamination from endogenous bowel flora. One further practical advantage of a short 2-day course of metronidazole is that it does not interfere with early hospital discharge around the third or fourth postoperative day.

Since there has been no significant evidence for strict anaerobes developing resistance to metronidazole over many years of widespread and varied use, a short course of the drug seems unlikely to precipitate the emergence of bacterial resistance.

Acknowledgements

We wish to thank all members of the Surgical Division of the Victoria Infirmary, Glasgow, for allowing us to study their patients for this trial.

We are also indebted to Miss I. K. Morton, Principal Pharmacist, and the ward nursing staffs for their efficient help in randomizing the allocation of patients to the trial.

Suppositories were kindly supplied by Messrs May & Baker Ltd, Dagenham, Essex, who also carried out estimation of serum metronidazole levels.

A double-blind trial of a single intravenous dose of metronidazole as prophylaxis against wound infection following appendicectomy

M. J. GREENALL, A. BAKRAN, I. R. PICKFORD, J. A. BRADLEY,
A. HALSALL, J. MACFIE, M. ODELL, E. MARY COOKE,
CHRISTINE LINCOLN AND M. J. MCMAHON*

SUMMARY

One hundred patients undergoing appendicectomy through a right iliac fossa incision were randomized to receive normal saline or 500 mg metronidazole as an intravenous infusion during the operation. One patient in the saline group developed an erythematous rash. There were 13 wound infections (as defined by the discharge of pus), 12 (out of 51) in the saline group and 1 (out of 49) in the metronidazole group. Bacteroides *spp. were frequently cultured from the lumen of removed appendices and from pus obtained from infected wounds. This work supports the value of metronidazole but suggests that a single-dose regimen is adequate for prophylaxis.*

AFTER appendicectomy a high proportion of infected wounds has yielded *Bacteroides* spp. (Leigh et al., 1974) and a previous study (Willis et al., 1976) has shown that a regimen of metronidazole suppositories and subsequently tablets given for a period of 1 week significantly reduced the incidence of wound infection.

We felt that the use of suppositories held certain disadvantages, and that treatment for 7 days might be unnecessary. Metronidazole administered as an intravenous infusion has been found safe and effective in the treatment of anaerobic infections (Selkon et al., 1977), and a single 500-mg dose infused over 20 min produced a mean rise of 11·7 μg/ml 30 min after administration had ceased in 14 patients (Eykyn and Phillips, 1977). As these serum levels appeared to compare favourably with those achieved by treatment with metronidazole suppositories (Houghton and Templeton, 1978), we have investigated the efficacy of a single intravenous dose of 500 mg of metronidazole administered during appendicectomy as prophylaxis against wound infection.

Patients and methods

Patients who underwent appendicectomy via a right iliac fossa approach in the General Infirmary at Leeds during two periods of time between July 1977 and April 1978 were included in the study. A total of 116 patients aged between 5 and 73 years was included but 16 were rejected before the code was broken (Meckel's diverticulitis, 1; administration of additional antibiotics, 4; data mislaid, 3; failure to administer the infusion or adhere to the protocol, 8). The study was carried out using a randomized, double-blind technique. Identical infusion bottles containing 500 mg metronidazole in 100 ml saline or 100 ml physiological saline were stored in numbered sequence in the operating theatre. When a patient was taken to theatre for appendicectomy the numbered bottle was given to the anaesthetist who commenced the infusion once the anaesthetic had been induced and allowed the 100 ml to run in over approximately 10 min. At the end of the procedure data were recorded by the surgeon on a similarly numbered card. The wound was examined daily by the surgeon whilst the patient was in hospital and also at the first visit to the outpatient department. An infection was defined as the discharge of pus from the wound.

A swab was taken from the lumen of the appendix and also from all wound infections which appeared during inpatient stay. All the lumen swabs but only about half the wound swabs were placed immediately into Robertson's meat broth and plated out within 30 min. The Robertson's meat broth was subcultured at 24 h. The aerobic media used for inoculation and subculture were blood agar and MacConkey agar and the anaerobic pre-reduced media used were blood agar, neomycin blood agar and kanamycin (100 μg/ml) and vancomycin (7·5 μg/ml) blood agar. The wound swabs not transported in Robertson's meat broth were inoculated directly on to these media. The time between taking the swab and inoculation of the media was variable, but on occasions it was in excess of 4 h. Bacteria were identified by standard methods. Anaerobic Gram-negative bacilli were designated *Bacteroides* spp.

The code was broken when 100 patients had satisfactorily completed the trial.

Results

Fifty-one patients received saline and 49 metronidazole. The two groups were well matched except with respect to the frequency of wound drainage (*Table I*), which was more commonly employed in the control group.

Pus producing wound infection was seen in 1 wound from the metronidazole group (2 per cent) and in 12 from the saline control group (24 per cent). This difference was significant at $P = 0{\cdot}002$ using Fisher's exact test. Reddening of the wound, which settled without additional treatment and did not result in a discharge of pus, was seen in a further 4 wounds, 2 in the metronidazole group and 2 in the control group.

The prevalence of various species of bacteria recovered from the appendix lumina and from the pus of the infected patients is shown in *Tables II* and *III*. All infected wounds discharged pus between 3 and 14 days after appendicectomy.

The patient who was treated with metronidazole and developed an infected wound did not have a drain but 3 of the patients in the saline group who became infected did have wound drains.

Discussion

A wound infection resulting in the production of pus was found in 12 of the 51 patients who received prophylaxis with intravenous saline. This infection rate of 24 per cent is similar to rates reported in other recent series in which no antibiotic prophylaxis was employed (Rickett and Jackson, 1969; Benson et al., 1973; Bates et al., 1974).

Leigh et al. (1974) recovered *Bacteroides* spp. from 90 per cent of infected wounds after appendicectomy. Our overall recovery rate of 40 per cent was due to our failure to isolate *Bacteroides* spp. from dry swabs, but the rate was 80 per cent from the swabs sent in

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Already used widely in ● serious infections

INJECTABLE

ZINACEF

cefuroxime sodium

Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics.

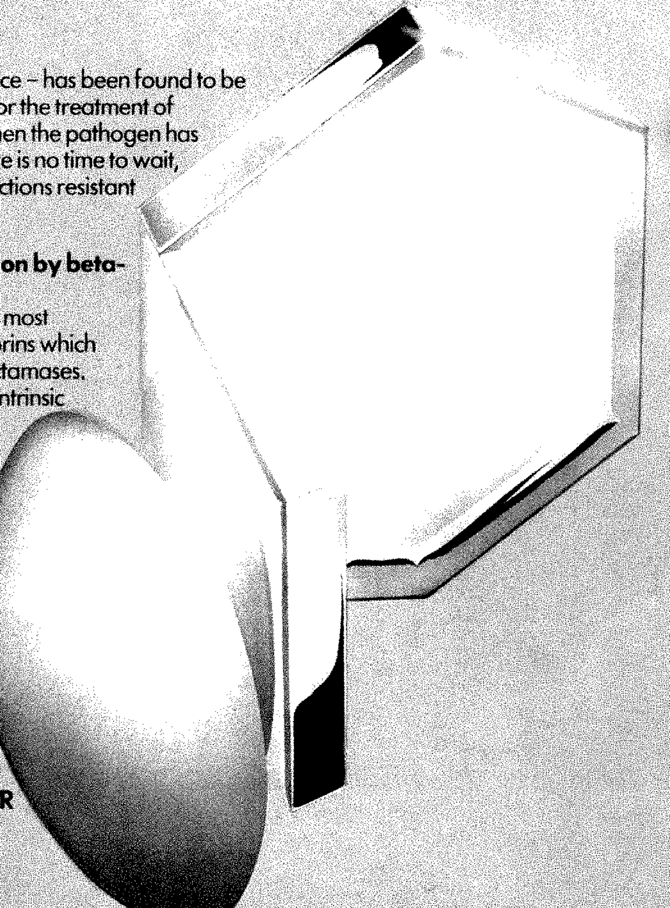
Zinacef resists destruction by beta-lactamases

A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.

Zinacef is effective against:

- **most common pathogens**
- **many uncommon pathogens**
- **multi-antibiotic resistant pathogens**

ZINACEF, A BROADER SPECTRUM THAN MOST ANTIBIOTICS



Prescribing information

Presentation

Vials of 250mg, 750mg and 1·5 grams and infusion pack of 1·5 grams. All containing cefuroxime as cefuroxime sodium.

Indications

Serious bacterial infections, especially where the organisms have not yet been identified.

Conditions include:

Chest infections
Septicaemia
Soft-tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Ear, nose and throat infections
Meningitis
Gonorrhoea

Dosage

Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 grams t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary, giving total doses of 3 grams to 6 grams daily.

Infants and Children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.

Neonates: 30 to 100mg/kg/day in two or three divided doses.

Gonorrhoea: Single dose of 1·5 grams (2 × 750mg i.m. into different sites).

Contra-indications

Hypersensitivity to cephalosporins.

Precautions

Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.

As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.

Zinacef does not interfere with enzyme-based tests for glycosuria. Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.

Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.

Reduce dosage when renal function is markedly impaired.

Cephalosporins at high dosage should be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.

Side effects

Adverse reactions are rare and generally mild and transient, e.g. rashes, gastro-intestinal disturbance, candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs test, transient rises in serum liver enzymes and transient pain (after i.m. injection).

Storage

Protect from light.

Product Licence number: 4/0263

Price to Hospital (exclusive of VAT)

5 × 250mg	£0·70 per vial
5 × 750mg	£2·10 per vial

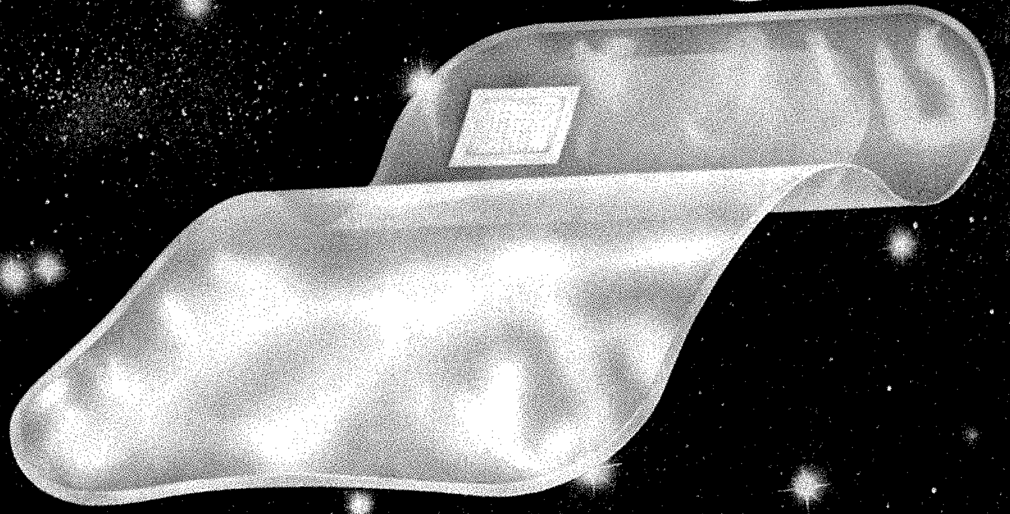
Hollister conquers gas



At last - a highly effective flatus filter from Hollister

No leaks, no odour — Hollister have made sure that this new deodorising flatus filter is really effective and trouble-free.

Every colostomy patient knows the discomfort and embarrassment that occurs when a stoma bag swells up with flatus. Now Hollister have developed a flatus filter system that solves this problem successfully. Laboratory trials have proved its reliability.

Gas is released automatically through the unique Hollister* deodorising filter — packed with thousands of tiny odour-trapping granules of activated charcoal.

No leaky filter, no odour, no more discomfort or embarrassment. It really works. Hollister have conquered gas!

Robertson's meat broth. This organism is clearly important in wound infections following appendicectomy. Nevertheless, we cultured a total of four other organisms from the wounds of patients who had not received metronidazole. Although the effectiveness of metronidazole as an agent for use against *Bacteroides* is now well established (Whelan and Hale, 1973; Willis et al., 1974, 1976, 1977), most of the remaining organisms isolated here do not lie within its spectrum of activity. There is evidence, however, that obligate anaerobes such as *Bacteroides fragilis* may inhibit phagocytosis (Ingham et al., 1977) and thereby allow other organisms to multiply. Such a mechanism might explain the effectiveness of metronidazole in reducing the incidence of infections involving a wide spectrum of organisms.

In this trial we have found that a single intravenous injection of metronidazole produced a reduction in the incidence of infection similar to that achieved by a combined suppository and tablet regimen lasting 7 days. Although Willis et al. (1976) 'considered it inappropriate, however, to use the intravenous route for evaluating the drug as a prophylactic agent', we feel that it has certain advantages in routine practice.

The value of antibiotics for the prevention of wound infection after appendicectomy is at present rather unclear. Although some reports claim marked benefit from their use (Rickett and Jackson, 1969; Longland et al., 1971; Bates et al., 1974), this impression has not been universal (Magarey et al., 1971). There is at least agreement between reports upon the value of metronidazole, although no trial has yet set out to compare this drug with an antibiotic.

We conclude that a single intravenous dose of metronidazole administered at the time of appendicectomy is a convenient, safe, cheap and effective method of reducing wound sepsis rates.

Acknowledgements

We would like to thank Mr E. A. Benson, Mr R. L. Doig, Mr G. L. Hill, Professor D. Johnston, Mr J. H. Shoesmith and Mr F. G. Smiddy for permission to carry out this trial upon patients admitted under their care. We thank the anaesthetic and theatre staff of the General Infirmary at Leeds for their cooperation, and Dr J. Collier and Miss E. M. Colhoun of May and Baker Ltd for the supplies of metronidazole and placebo and for their help with the organization of the trial.

Short term metronidazole therapy contrasted with povidone-iodine spray in the prevention of wound infection after appendicectomy

R. J. SALEM, J. JOHNSON AND P. DEVITT*

SUMMARY

In a prospective, randomized trial metronidazole was found to be significantly better than povidone-iodine in reducing the incidence of wound infection after appendicectomy ($P<0{\cdot}005$). The metronidazole was given as a 3-day course and was found to be as effective as the established 7-day course. Over 65 per cent of the wound infections presented after the patients had been discharged from hospital.

WOUND infection is a common complication of appendicectomy (*Lancet*, 1970, 1971) increasing both the morbidity and the length of stay in hospital. Previous work in this hospital (Gilmore and Martin, 1974) has shown that povidone-iodine sprayed into the incision during closure reduces wound infection from 16 to 8 per cent. More recently the use of metronidazole (Willis et al., 1976) has shown a reduction in the wound infection rate from 22 to 10 per cent.

We report here the results of a prospective trial comparing short term (3 days) metronidazole administration with povidone-iodine spray for the prevention of wound infection.

Patients and methods

All the patients admitted to the Royal Berkshire and Battle Hospitals for emergency appendicectomy were randomly allocated to one of the treatment groups. Group 1 received a metronidazole 1-g suppository 2 h before operation and every 8 h after operation for a total of 3 days. If the oral form could be tolerated postoperatively 200 mg every 8 h was administered instead of the suppository. Children under 10 received 0·5-g suppositories. Group 2 received povidone-iodine dry powder into the wound after closure of the peritoneum, sprayed from a distance of 20 cm for approximately 8 s, so that a good coating of powder was visible in and around the wound. A further dose was applied after closure of the skin.

A standard appendicectomy technique was performed by all the surgeons involved. Wounds were inspected by an independent observer postoperatively, and the patients were reviewed at a special follow-up clinic between 3 and 5 weeks after leaving hospital. Patients were also asked to attend the ward should any discharge from the wound occur during this period.

A wound infection was defined as any purulent or infected sero-sanguineous discharge from the wound.

Results

One hundred and twenty-nine patients were entered in the trial in a 3-month period. Four patients were withdrawn from the trial. Two had received systemic antibiotic prophylaxis for suspected rheumatic heart disease, a third had an incomplete course of metronidazole and the fourth had systemic antibiotics for pneumonia. None of these patients developed a wound infection. A further 15 patients failed to attend the follow-up clinic but did reply to a postal inquiry and have been included in the trial.

There were 65 patients in the metronidazole group and 60 in the povidone-iodine group. Both groups matched for age and sex. Wound infection occurred in 4 patients in the metronidazole group (6·2 per cent), which was significantly less than in the povidone-iodine group in which there were 16 patients with infection (26·6 per cent) ($P<0{\cdot}005$—using χ^2 with Yates' correction). Eight of these infections (2 metronidazole, 6 povidone) were superficial and had healed within 2 or 3 days. The infection rate in relation to the severity of the appendicitis is shown in *Table I*.

The average length of stay in hospital was 4·9 days in the non-infected patients but 8·6 days in those infected. Thirteen of the wound infections presented after discharge from hospital and 3 of these patients (all in the povidone group) required readmission. Culture swabs of the wound infections were only available in 9 cases—7 of which showed growth with bacteroides organisms (all in the povidone group).

Table I: INFECTION RATE RELATED TO SEVERITY OF APPENDICITIS

	Metronidazole		Povidone-iodine	
Severity	No.	Infected	No.	Infected
Normal	14	0	12	1
Acutely inflamed	41	1	34	8
Gangrenous	5	1	7	2
Perforated	5	2	7	5
Total	65	4	60	16

Discussion

Because of good back-up facilities provided by the local family practitioners, we are able to send many of our patients home earlier after operation than is usually advocated (*Lancet*, 1970). For this reason nearly two-thirds of the wound discharges occurred after the patients had left hospital.

The patients were asked to attend the ward should they develop any complication with their wound, so that culture swabs could be taken. However, several did not attend and the diagnosis of wound infection was made retrospectively at the special follow-up clinic and included any wound discharge, however minor. These minor discharges, possibly due to iodine irritation, may explain the high rate of wound infection in the povidone-iodine group and it is a pity that for ethical reasons based on previous reports (Gilmore and Martin, 1974; Willis et al., 1976) a control group was not included in the design of our trial. Even if these minor wound discharges are excluded, metronidazole is still significantly better than povidone-iodine ($P = 0{\cdot}02$).

Unfortunately as many patients did not attend for bacterial culture swabs to be taken, conclusions regarding the bacteriology cannot be made, but it is

interesting to note that in the povidone group at least 7 of the 16 wound infections grew bacteroides and in 4 this was in pure culture.

Although the numbers in our trial were smaller, we were unable to reproduce the previous results obtained from our hospital by Gilmore and Martin (1974) using povidone-iodine. This was surprising since there had been little change in the proportion of severe cases, in the age and sex distribution, and no alteration in the composition of the povidone-iodine spray. If the minor wound discharges are excluded there was still a wound infection rate of 16 per cent which was similar to the control group in the previous study. However, at the time of the previous study, anaerobic culture techniques for bacteroides organisms were not as stringent as at present and perhaps some wound discharges were considered sterile and therefore not considered a wound infection. McClusky (1976) found that povidone-iodine solution did not prevent wound infection after general surgical operations and Galland et al. (1977) drew similar conclusions using povidone-iodine spray.

The incidence of wound infection after appendicectomy for a gangrenous or perforated appendicitis is extremely high. Three of the 4 cases of wound infection in the metronidazole group occurred in such cases. It would seem, therefore, that although metronidazole is fairly effective in reducing the incidence of wound infection, further measures such as delayed primary suture or additional prophylactic antibiotics should be considered in cases of gangrenous or perforated appendicitis.

We have found a 3-day course of metronidazole to be equally effective as the previously described 7-day course (Willis et al., 1976). Animal experiments (Burke, 1961) suggest that systemic antibiotics given before or within 3 h of bacterial inoculation of a wound will suppress bacterial infection of that wound. Since most infections after appendicectomy are due to endogenous bacterial contamination it will be interesting to see if a two-dose course of metronidazole will also be effective in reducing wound infection.

Left renal vein ligation in surgery for abdominal aortic aneurysm

N. D. FOX AND R. S. TAYLOR*

OCCASIONALLY, during surgery on the abdominal aorta, division of the left renal vein is required for technical reasons. In this paper we present 6 patients with abdominal aortic aneurysms in whom the left renal vein was divided but not reconstituted. There were no deaths and all 6, now between 6 months and 3 years after operation, show no significant disturbance of renal function.

Patients and methods

All 6 patients (4 males and 2 females) had abdominal aortic aneurysms. Four were elective cases, one aneurysm was expanding and required urgent operation and the other was ruptured.

In most cases division of the left renal vein was required to obtain safe control of the aorta above the neck of the aneurysm or because the vein was densely adherent to the aorta. In one a retro-aortic vein was accidentally torn. In all cases the vein was divided well to the right so as to avoid the left adrenal vein, the most medial tributary.

Blood urea estimations were carried out preoperatively on all patients and serum creatinine was measured in 2 of the 4 elective cases. Postoperative investigations were performed within 6 months of leaving hospital and included blood urea and serum creatinine estimations and an intravenous pyelogram. It can be seen from *Table I* that all patients maintained satisfactory renal function and those with blood urea and creatinine levels close to the upper limit of normal have normal intravenous pyelograms. Of particular interest is the observation that all 6 patients have a normal blood pressure.

Table I: DETAILS OF THE SERIES AND POSTOPERATIVE RENAL FUNCTION TESTS

Case	Age (yr)	Sex	Operation	Blood pressure (mm Hg) Preop.	Blood pressure (mm Hg) Postop.	Blood urea (mmol/l) Preop.	Blood urea (mmol/l) Postop.	Serum creatinine (mmol/l) Preop.	Serum creatinine (mmol/l) Postop.	IVP

J. N.	58	F	Elective	170/110	160/95	6·2	7·0	—	105	Normal

Discussion

The major tributaries of the left renal vein are the gonadal veins and the left adrenal vein. The left inferior phrenic vein usually joins the left adrenal vein but may drain directly into the left renal vein. The gonadal vein anastomoses with the lumbar veins and capsular veins drain into the lumbar system. De Laurentis and Iyenager (1970) demonstrated these and other collateral veins draining the kidney after left renal vein ligation using an ingenious radiological technique cannulating a vein in the pampiniform plexus. Szilagyi et al. (1969) reported 20 patients in whom they temporarily divided and reconstituted the left renal vein with no harm to the patients. Neal and Shearburn (1967) reported 11 patients in whom the left renal vein was permanently transected. There were 3 deaths in their series but no death was attributable to left renal vein ligation. Simon et al. (1972) reported 13 patients in whom the left renal vein or a major tributary was divided to allow end-to-end anastomosis in splenorenal shunts for portal hypertension. There were 5 deaths due to liver disease. None of these patients had any impairment of renal function and the 8 survivors all had normal intravenous pyelograms and renal function tests. Only one example of major damage to the kidney has been found in a review of the literature; Royster et al. (1974) have reported one patient with a ruptured aneurysm who died several days after operation and in whom post-mortem examination revealed venous infarction of the left kidney following left renal vein ligation.

Conclusion

Left renal vein ligation is a safe procedure. There are adequate collateral channels into which venous return from the left kidney can drain, and, provided that the left renal vein is divided far enough to the right to preserve the adrenal and gonadal veins, no harm should come to the left kidney.

Acknowledgement

We wish to thank Mr R. M. Greenhaigh, Charing Cross Hospital, for permission to report 2 of the cases.

The morbidity of carotid endarterectomy

D. BOUCHIER-HAYES, A. DE COSTA AND W. A. L. MACGOWAN

SUMMARY

The results of 72 carotid endarterectomy operations carried out by three consultant surgeons were analysed. Thirty-eight operations (32·8 per cent) were performed in patients with mild or resolving stroke and 33 operations (45·9 per cent) in patients with transient ischaemic attacks and/or amaurosis fugax. Five patients (7 per cent) died in the early postoperative period, 2 as a result of strokes and the others from cardiac causes. Seventy-six per cent of patients had a satisfactory long term result, remaining free from stroke, blindness or recurrent transient ischaemic attacks over the follow-up period of 1–7 years.

There were 10 patients (13·8 per cent), including 2 who died, who developed early postoperative neurological deficits; 4 (5·5 per cent) had transient defects and 6 (8·3 per cent) had permanent deficits. Of these patients, 4 had proved occlusions of the reconstructed artery. In 3 patients, cerebral embolization during operation was suspected as the cause. There were, in addition, 2 asymptomatic patients whose reconstruction was shown to be occluded on follow-up postoperative angiography. The continued absence of symptoms, therefore, is no guarantee that the reconstruction is patent and some more objective method of assessment is necessary if the results of carotid endarterectomy are to be critically analysed. The incidence of neurological deficits could, it is believed, be reduced by greater experience with the operation, the routine use of peroperative intra-arterial shunting and peroperative angiography to confirm the patency of the reconstruction.

CEREBROVASCULAR accidents—strokes—are a common cause of death and serious disablement. The incidence in Ireland is 200 per 100 000 population and in Britain it is 185 per 100 000 population; 34·9 per cent of the patients die within 3 weeks of onset of the stroke and 54·1 per cent die within 1 year (Radic et al., 1977). Stroke is, therefore, a major health problem and little progress has been made in its management. Prevention remains a worth-while goal.

Forty per cent of patients with stroke have the principal vascular occlusion confined to the extracranial vasculature and indeed 75 per cent of patients with ischaemic stroke have at least one obstructive lesion at a surgically accessible site (Fisher, 1951; Engell, 1973). Medical management of the carotid lesion based on the prevention of thrombotic occlusion of the internal carotid or distal embolism is still controversial. The efficacy of either anticoagulants or antiplatelet agents in reducing the mortality from stroke has not yet been proved.

Studies have shown the superiority of surgical over medical management of the extracranial vessel lesions (Bauer et al., 1969; Fields et al., 1970). These studies and other reports, most notably those of Javid et al. (1974) and Thompson and Talkington (1976), confirm the value of surgical management of internal carotid disease both in the reduction of transient ischaemic attacks and the prevention of death from stroke. The purpose of this retrospective study is to review our experience with the operation of carotid endarterectomy for internal carotid artery disease, to analyse the complications of the operation and to determine the effectiveness of the procedure.

Patients and methods

The records of 64 patients who had a carotid endarterectomy operation in St Laurence's Hospital, Dublin, during the period 1970–7 were reviewed. Seventy-two operations were carried out on the internal carotid artery. The operations were performed by the three consultants on the surgical professorial unit. In 56 patients the operation was unilateral and in 8 patients bilateral operations with a suitable interval between them were performed. The age range was 42–72 years. There were 17 females and 47 males.

Clinical features

The presenting clinical features (*Table I*) were those classically associated with this disease; transient hemispheric attacks, amaurosis fugax and neck bruits. One patient presented with a palpable lump in the neck caused by the atheromatous deposit in the vessel. In only one patient was the neck bruit asymptomatic. Twenty-four of the patients had associated systemic hypertension.

Table I: CLINICAL FEATURES IN PATIENTS UNDERGOING CAROTID ENDARTERECTOMY

Mild or resolving stroke	38
Transient ischaemic attack	30
Amaurosis fugax	29
Neck bruit	24
Hypertension	24
Dysphasia	13
Headache	8
Completed stroke	4
Palpable mass in neck	1

Angiographic pattern of the disease

The disease was unilateral in 37 patients and bilateral in 27. The atheromatous lesion was an ulcerating plaque in 22 and a stenosing lesion in 53. The contralateral carotid was totally occluded in 3 patients. Only one patient had a totally occluded internal carotid artery operated on (*see* below).

Indications for operation

It is the practice of this unit to operate on patients with symptomatic, angiographically significant lesions of the internal carotid artery, either stenosis or an ulcerating plaque. Operation was rarely performed for advancing stroke or for patients with recently occluded vessels. Indeed, only one patient was operated on for advancing stroke with a recently occluded internal carotid artery. In 38 of 72 operations the indication was mild or resolving stroke. The remaining operations were performed for patients with either transient ischaemic attacks and/or amaurosis fugax.

Investigations

All patients were assessed by a neurologist and then subjected to the definitive diagnostic investigation—carotid angiography. Bilateral biplane carotid angiography with careful cerebral cross-flow studies was performed in the majority of patients. Four-vessel angiography was reserved for those patients with symptoms of vertebral–basilar disease, significant differences

---

* Surgical Professorial Unit, Royal College of Surgeons in Ireland, At St Laurence's (Richmond) Hospital, Dublin.

in upper limb pulsations or blood pressure and basal neck bruits.

Operation

The operation was performed under a general anaesthetic using halothane. An intra-arterial pressure transducer was inserted into a radial artery to monitor the arterial blood pressure and the blood pressure was maintained at optimum levels during the operation. Cerebral activity was monitored continually by an electroencephalogram (EEG). The carotid vessels were exposed through an oblique incision along the anterior border of the sternomastoid. The hypoglossal and vagus nerves were carefully identified. Internal carotid artery stump pressures were usually measured but were not regarded as the determinant for intraluminal shunting. An intraluminal shunt was used prophylactically when there was either significant contralateral disease or poor cerebral cross-circulation. Therapeutic shunting was employed if the EEG showed evidence of cerebral ischaemia during the operation. Heparin, 5000 units, was given intravenously just before clamping the carotid vessels. A standard open thrombo-endarterectomy was performed, usually closing the defect by a vein patch.

A peroperative angiogram was performed routinely over the last 2 years of the study.

Postoperative management

The presence of a new neurological deficit or the worsening of a previous defect was assessed as soon as the patient was conscious. The wound was drained for 48 h and heparin (5000 units every 8 h) was given subcutaneously for 24-48 h. An antiplatelet agent was then used, such as aspirin or dipyridamole, for 6 weeks. Hypertension was controlled if necessary.

Results

Mortality

There were 5 postoperative deaths—a 7 per cent mortality. Two patients died within 48 h of surgery from myocardial infarction. One patient was successfully resuscitated from an intraoperative cardiac arrest only to die 2 h later as a result of massive haemorrhage from a peptic ulcer. The reconstructed vessels were patent at autopsy in all 3 cases. The other 2 patients died from cerebrovascular accidents and they are discussed in more detail below.

Morbidity

Local complications: One patient had a permanent small visual defect after operation, presumably from embolism to a retinal vessel. Three patients developed a haematoma in the neck which required evacuation. Nine patients had transient injuries to the nerves close to the operative field. There were 6 patients with transient hypoglossal nerve palsies. Two patients had transient lesions of the mandibular branch of the facial nerve and 1 patient had evidence of damage to the superior laryngeal branch of the vagus nerve. Nearly all these patients had an uneventful recovery from the nerve damage but 3 of the patients with the XIIth nerve damaged still showed a neurological defect some months after the operation.

Neurological complications: Ten patients (13·8 per cent), including 2 who died, developed major neurological deficits postoperatively. These deficits manifested clinically as hemiplegia in 6 previously neurologically intact patients and as a significant worsening of a neurological problem in 4. In 8 patients the problem was first noted on the day of operation. Two patients developed signs on the second and third postoperative days.

There were 6 permanent deficits (8·3 per cent): 2 patients died, 2 failed to show any resolution and 2 were left with a residual mild weakness of the hand. There were 4 transient neurological deficits (5·5 per cent) which cleared completely.

In these 10 patients the reconstructed artery was shown to be occluded in 4 at autopsy or on postoperative arteriogram; in 1 patient, acute thrombotic occlusion of the internal carotid artery distal to a stenosis was found at operation; in another, a wound haematoma probably caused compression of the internal carotid artery. The cause of the stroke in the remaining 4 patients could not be established unequivocally, but in 3 the operative and clinical findings favoured a diagnosis of cerebral embolism.

In none of the 10 patients was an abnormality detected on the peroperative EEG recordings. In only 2 of the patients was a shunt inserted and neither developed a permanent deficit. Seven of the remaining 8 patients met our criteria for shunting but were not shunted.

Follow-up

Of the 64 patients, 2 were not traced and 5 died in hospital, leaving 57 patients for review. The minimum follow-up period was 1 year and the longest, 7 years. Forty-nine patients (76 per cent) had a satisfactory outcome with freedom from further transient ischaemic attacks or strokes. There were 4 deaths, 1 from a lung tumour, 1 from a brain tumour and 2 from strokes. One of these strokes was an early postoperative complication, the patient dying some months later. A second patient died at 2 years of an ipsilateral cerebrovascular accident.

Two patients developed non-fatal strokes, one at 2 years and the other at 5 years postoperatively. In neither was the reconstructed artery implicated; in one an ipsilateral angiogram showed a patent reconstruction and in the other the opposite carotid territory was involved but angiography was not performed. Two patients had transient ischaemic attacks; in both the reconstructed vessel was patent on angiography.

Patency of reconstruction: Postoperative angiography was performed in 13 patients: in 9 the reconstruction was patent and satisfactory and in 4 the internal carotid artery was occluded. Two of these 4 patients were asymptomatic and the findings were unexpected.

There were 8 proved early occlusions of the endarterectomized carotid artery demonstrated by angiography or at reoperation or autopsy—an incidence of 11 per cent.

Discussion

The long term results of carotid endarterectomy in this and other series are satisfactory (*Table II*). Nearly 80 per cent of patients remain free from stroke, transient ischaemic attacks, transient or permanent blindness. The operation has a significant mortality and morbidity. The 7 per cent mortality rate in this series is similar to that found by others (*Table II*). Three of 5 patients died directly or indirectly from cardiac causes. The incidence of mortality is influenced by the clinical severity of the carotid disease, associated ischaemic heart disease and the experience of the surgical team.

The morbidity associated with carotid endarterectomy is either of local or of neurological origin. The local complications are usually more annoying than serious, although wound haematoma can compress the internal carotid artery with serious consequences, as occurred in 1 of our patients. Lesions of the VIIth, Xth and XIIth nerves are embarrassing not only to the patient but also to the surgeon. Damage to the mandibular branch of the facial nerve can be avoided by ensuring that the upper end of the incision remains 2·5 cm below the posterior angle of the mandible. Extending the incision posteriorly to the mastoid process improves exposure, avoids the mandibular branch of the VIIth nerve and lessens the risk of retractor damage to the XIIth nerve. Careful identification and handling of both the Xth and XIIth nerves should prevent permanent damage.

The most devastating complication of carotid endarterectomy is a stroke. The total number of neurological deficits in this series was 10 (13 per cent). This incidence is high, and was associated with significant mortality and morbidity. Fortunately, 6 of the 10 patients either fully recovered or were left with a minor disability. This incidence, at first sight, appears to be greater than that usually recorded; however, it includes all postoperative neurological deficits, both transient and permanent, since the difference between them is one of degree. Also included are the strokes that result in death: it is not clear in many reports whether these are included in the calculation of permanent deficits. It can be seen from *Table III*, where the incidence of transient and permanent neurological deficits in this and other series is presented, that our total incidence is similar to that of others. Most reports on carotid endarterectomy are from centres well versed in the technique and they reflect current rather than overall achievements (De Weese et al., 1973; Thompson and Talkington, 1976; Collins et al., 1978). This series is small and includes our total experience with this procedure. We have previously demonstrated a correlation between the experience of the operating team and the success of a vascular reconstruction, namely in femoropopliteal reconstruction (MacGowan, 1969). Thompson has reported a similar correlation in his own large personal series of carotid endarterectomies (Thompson and Talkington, 1976). It is also probable that the results commonly reported in the surgical literature are not a true reflection of the general achievements with carotid endarterectomy. This is borne out by a recent study of 228 consecutive carotid endarterectomies done by the members of the neurosurgical and vascular services of a large institution in a mid-Western state of America (Easton and Sherman, 1976). This independent review revealed a combined mortality and morbidity from postoperative stroke of 21·1 per cent.

It is important to reduce to a minimum the occurrence of neurological deficits after carotid endarterectomy; for the majority of patients a permanent neurological deficit is a disaster which may result in either death or ruinous morbidity. A transient deficit is also a failure, although with less serious consequences for the patient. Of course where the neurological complications induced by surgical therapy are many the overall results of surgery may approach those of long term expectant therapy and the procedure can then no longer be advocated with confidence.

Table II: MORTALITY AND LONG TERM RESULTS OF CAROTID ENDARTERECTOMY

Authors	Operative mortality (%)	Normal or improved long term (%)	Length of follow-up
Present series	7	76	1–7 yr
Fields et al. (1970)	3·6	47	42 mth (mean)
De Weese et al. (1973)	1	88	5 yr
Thompson and Talkington (1976)	2·3	88·9	1–13 yr

Table III: INCIDENCE OF NEUROLOGICAL DEFICITS AFTER CAROTID ENDARTERECTOMY

Authors	Transient deficits (%)	Permanent (%)	Total (%)
De Weese et al. (1973)	15	16	21
Fields et al. (1970)	1·8	7·7	8·5
Collins et al. (1978)	3·0	2·2	5·2
Thompson and Talkington (1976)	0·9	0·7	1·6
Present series (1978)	5·5	8·3	13·8

Postoperative neurological deficits result from cerebral hypoperfusion secondary to clamping of the internal carotid, cerebral embolization or acute thrombosis of the reconstructed vessel. The vigorous debate about the relative importance of either cerebral embolization or hypoperfusion has tended to obscure the role of acute thrombotic occlusion of the reconstructed internal carotid artery in the genesis of postoperative stroke. In this series the commonest proved cause of a neurological deficit was an acute thrombotic occlusion. In 4 of 10 patients with neurological deficits the endarterectomized internal carotid artery was shown to have occluded and in only 2 could occlusion be unequivocally excluded as the cause. Others have recorded similar experiences; Lindberg et al. (1975) reported a 10 per cent incidence of acute thrombotic occlusion in their first 100 operations.

The importance of this observation is that it should be possible to detect acute thrombotic occlusion or technical factors favouring its development by peroperative angiography. Many have disputed the value of routine peroperative angiography at the completion of carotid endarterectomy (Andersen et al., 1978). However, there is no doubt that an impressive harvest has been reported by its proponents. Blaisdell reported a 25 per cent incidence of unsuspected defects detected by peroperative angiography in his earlier experiences with carotid endarterectomy in 1967, and he still advocates routine angiography (Blaisdell et al., 1967; Blaisdell, 1978). More recently, Rosental reported an 8 per cent yield of defects requiring correction detected by peroperative angiography (Rosental et al., 1973). We have recently discovered serious unsuspected defects in 2 patients by peroperative angiography and these were corrected without incident. Clearly an operation which is undertaken to correct an angiographic defect should be shown to have achieved that objective at the time of the operation.

The incidence of early thrombotic occlusion is probably greater than suspected. Certainly the continued absence of symptoms referable to the operated side is no guarantee that the reconstruction is patent, as was demonstrated in 2 of our patients who had follow-up angiography before operation on the other side. Angiography revealed unsuspected occlusion of the recently endarterectomized carotid artery. It is mandatory to confirm the patency of a reconstruction before correcting the contralateral side.

Proper evaluation of carotid endarterectomy in the prophylaxis of stroke requires objective evidence of continuing patency. As, until recently, this could only be obtained by repeated angiography, this evaluation has still to be made. It is to be hoped that recent improvements in non-invasive assessment, especially in carotid imaging with pulsed wave Doppler ultrasound, will finally resolve this issue.

The incidence of either of the other two mechanisms commonly claimed to explain neurological deficits, namely cerebral hypoperfusion and embolization, is difficult to determine. Embolization must be a significant cause of postoperative neurological deficit as spontaneous emboli are responsible for the symptoms that prompt surgery. The incidence of platelet–fibrin emboli during carotid endarterectomy has been reported to be from 15 to 50 per cent; however, the diagnosis is frequenly inferential rather than direct (Akl et al., 1975; Bland et al., 1970). Certainly in our series there was strong inferential evidence that intraoperative cerebral embolization was responsible for 3 of the 10 postoperative neurological deficits. Every precaution must be taken during surgery to reduce the risk of embolization during carotid endarterectomy. Adequate exposure permitting gentle dissection of the carotid vessels is obviously essential. The timing of the procedure may also be of importance. Harrison and Marshall (1977) have reported an apparent periodicity in the thrombotic tendency of carotid lesions: patients operated upon within 4 weeks of a transient ischaemic attack were noted to have a greater incidence of thrombus adherent to the lesion than those in whom surgery was performed after a longer symptom-free interval.

Not only is it desirable to reduce the incidence of cerebral emboli, but it is also important to minimize the neurological consequences of such emboli. Hertzer and his colleagues at the Cleveland Clinic have recently introduced an intriguing twist to the controversy over routine intraoperative shunting during carotid endarterectomy. They suggest that cerebral embolization during dissection of the carotid artery is a significant factor in the aetiology of intraoperative neurological deficits and that carotid shunts may reduce the incidence of permanent stroke by supplying adequate blood to an embolized area to minimize the incidence of permanent neurological deficit (Hertzer et al., 1978).

Transient hypoperfusion of the ipsilateral carotid cerebral territory is yet another potential cause of postoperative stroke which has received considerable attention. Clearly there is a group of patients who are at high risk of inadequate cerebral perfusion during the period of carotid clamping (Callow et al., 1978). Uncertainty exists, however, as to which patients require protection and which method of protection is the best. In common with others we have not found either cross-circulation angiography or carotid stump pressures to be of predictive value (Smith et al., 1976; Gayliss and Mieny, 1977). We have had little experience with the use of local anaesthesia or a combination of it with neurolept analgesia instead of general anaesthesia (Connolly et al., 1977) but have relied upon continuous EEG recordings as a guide to the adequacy of cerebral perfusion. In the past this has not proved in our hands to be especially helpful, but we have recently been impressed with the sensitivity of more modern EEG recorders. We have no experience with such methods of cerebral protection during cross-clamping as hypercarbia, hypocarbia, induced systemic hypertension or hyperbaric oxygenation (Ehrenfeld et al., 1970). Until recently we adopted a policy of selective shunting for 'high risk' patients. This we have now abandoned because of uncertainty as to the accuracy with which such patients were identified. We now use an indwelling arterial shunt routinely during carotid endarterectomy for the following reasons: there are 'high risk' patients who may not be recognized as such; continuous perfusion via a carotid shunt may lessen the consequences of cerebral embolization; and shunting may facilitate a less hurried and meticulous reconstruction. The best results with carotid endarterectomy have been achieved by those who routinely used a shunt. Thompson's results are the bench-mark of carotid surgery (Thompson and Talkington, 1976): his incidence of mortality (0·4 per cent) and of permanent neurological deficit (0·7 per cent) should not only be the aim but the achievement of all who perform carotid endarterectomy for the prevention of stroke.

Synovial actinomycosis of the knee: a case report

RANJIT BOSE, R. KARJOO AND E. H. MAKAREM*

SYNOVIAL actinomycosis of the knee is not reported in the world literature. A case of actinomycosis of the hand due to a human bite is recorded but all other cases are visceral or cervicofacial (Rhangos and Chick, 1964).

Case report

A 32-year-old lady presented with a 4-month history of aching and swelling of the right knee and a past history of trauma with laceration of the skin over the knee. The wound had healed slowly with a small puckered scar. The knee was swollen with a discharging sinus. X-rays showed a huge soft tissue shadow around the knee with no calcification or bony change. Synovectomy was performed removing yellowish-brown hypertrophic tissue with areas of necrosis, calcification and sulphur granules. Histology revealed actinomycotic sulphur granules with Gram-positive mycelia and Gram-negative peripheral rods at right-angles to the main mass. The organism was sensitive to penicillin. The patient was treated with penicillin, 10 mega units, reduced to 4 mega units, daily for 3 months. The knee became pain-free but stiff with no swelling.

Eight years later the patient presented with pain and stiffness of the same knee and a small circumscribed swelling over the popliteal aspect. The X-ray of the knee remained unremarkable.

The popliteal swelling was excised and showed fragments of soft and fibrotic yellow shiny tissue that were infiltrated by acute and chronic inflammatory cells. There were also scattered giant cells throughout the specimen. Colonies of actinomyces were seen surrounded by acute inflammatory cells (*Fig.* 1). *Actinomyces israelii*, an anaerobic organism, was isolated from the tissue.

This organism was identified as follows: one blood agar plate was incubated anaerobically at 37 °C, a Sabouraud plate was incubated at 22 °C and the rest were incubated at 37 °C aerobically. The plates were kept for 10 days and were examined daily.

On the blood plates a few colonies were seen. They were rough, heaped up, small, irregular and opaque. In thioglycollate medium the organism grew as small fluffy balls below the surface of the medium. There was no growth on the aerobic plates. The colonies were Gram-stained which revealed pleomorphic, club-shaped, Gram-positive rods.

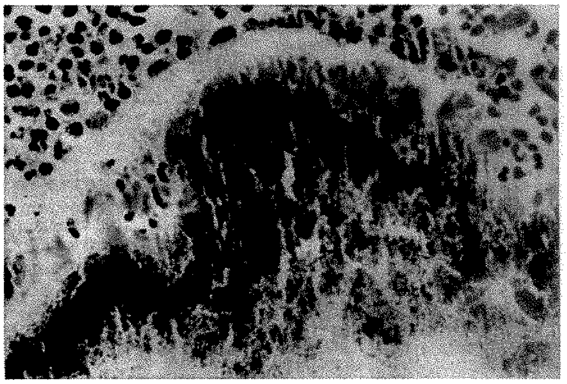

Fig. 1. Photomicrograph (high dry power) of fungi colony with acute inflammatory cells. (×36.)

Further biochemical tests showed that the organisms did not hydrolyse esculin, were catalase-negative, did not produce indole, reduce nitrate or liquefy gelatin.

The patient was treated with penicillin, 10 mega units, reduced to 4 mega units, daily for the next 4 months and remains symptom-free.

The clinical relevance of radiologically revealed Paget's disease of bone (osteitis deformans)

P. B. GUYER*

SUMMARY
Radiological and hospital records of 400 patients with Paget's disease that was shown radiologically have been examined in an effort to establish the clinical significance of the disease. Twenty-eight per cent of the patients were considered to have symptoms related to their disease, the most frequent symptom being bone pain, deformity and fracture. It appears that Paget's disease may predispose to the formation of urinary calculi. Malignant change and neurological and cardiovascular complications are rare, and osteitis deformans does not appear to predispose to osteoarthrosis.

JAMES PAGET first recorded the bone disease that now bears his name in 1877, and of his first patient he said: 'He suffered very little, and engaged in all the pursuits of a country gentleman' (Paget, 1877). His patient presented 20 years previously, with enlargement of the left tibia and femur; 3 years later the skull started to increase in size, and later still the right tibia and femur showed similar changes. The patient died 20 years after presentation following rapid swelling and pain in the left elbow and pleural effusion, indicating malignant change in his bone condition.

Béclère (1901) first recorded the radiological appearances of osteitis deformans, and in 1926 Roberts (a radiologist) and Cohen recognized the subclinical form of the disease. In subsequent papers the proportion of patients considered to be suffering on account of the disease varied from 5 to 80 per cent (Kasabach and Dyke, 1932; Dickson et al., 1945; McKusick, 1966; Evanson, 1974). An opportunity has therefore been taken to make a fresh assessment of the clinical significance of the bone condition in 400 patients with Paget's disease detected radiologically in the course of an epidemiological study of the disease (Barker et al., 1977; Guyer and Clough, 1978).

Patients and methods

Four hundred patients were collected in an unselected manner, as their Paget's disease was detected during a radiological examination, which was not necessarily their first, in local X-ray departments. In most the condition was revealed by plain or contrast examinations of the abdomen, or by skeletal examination, but in some it was detected initially by examinations of the skull, limbs or thoracic skeleton. One hundred patients who had already had extensive radiography now had this extended to provide full skeletal surveys; the extent of their previous skeletal radiology was the only factor considered in their selection. The diagnosis of the disease is based upon standard criteria (Campbell-Golding, 1971), there being three basic radiological forms. The commonest is the spongy form, with coarsening of the trabecular pattern, initially in a normal arrangement but later becoming disorganized. The cortex of the bone becomes thickened and loses its differentiation from the medulla. Areas of lucency are mixed with adjacent areas of sclerosis and eventually bending of the bone occurs due to softening. The second type is the amorphous form ('inactive'), with a dominant sclerosis of the bone which may show increase in diameter; deformity is rare. The third type is the osteoporotic form ('active'), which eventually changes to the spongy or amorphous form, but the process may take many years. Even though the bone is rarefied, it may yet be increased in thickness.

The request cards were examined for mention of Paget's disease, and the reports were studied to see how frequently the visible disease was reported. The case notes of the patients were examined for the clinical reaction to the X-ray report and for evidence that the clinicians attributed symptoms to the bone disease. Possible alternative explanations for pain were sought in the films of the lumbar spine. The notes and the radiographs were also examined for evidence of accepted complications of the bone disease (Campbell-Golding, 1971)—fractures, Paget's arthritis, urinary calculi, vascular calcification, spinal cord compression and sarcomatous change. The pelvis was also examined for evidence of sacroiliac joint fusion (Brunton, 1977). A note was made of both the age at onset of symptoms and the age at which the patient presented with the disease.

Results

Documented evidence of Paget's disease

The examination of the request card revealed that Paget's disease was mentioned in 73 of the 400 patients (18 per cent); in 34 of these the diagnosis had been established radiologically before the initial X-ray in our department. In the remainder, visible clinical deformity (27 patients) or elevation of the plasma alkaline phosphatase (12 patients) generated the request.

The initial radiological report on the anatomical area revealing Paget's disease mentioned the diagnosis in 361 of the 400 patients (90 per cent). The bone disease was generally reported in relation to deformity or fracture, but was, for instance in contrast examinations, often merely a brief comment at the end of the report, if it was mentioned at all.

Cognizance of the X-ray report by the clinician referring the patient for X-ray examination was recorded in the notes or letters of 223 of the 361 patients (62 per cent) in whom the disease was reported. In the 39 patients in whom the disease was not reported radiologically, it was recorded only once by the clinicians.

Table I: COMPLICATIONS OF PAGET'S DISEASE (400 PATIENTS)

Hip joint narrowing	188
Bone deformity	105
Vertebral wedging	39
Pathological fracture	24
Sacroiliac joint fusion	15
Increment fracture	13
Ureteric colic	12
Malignant degeneration	5
Deafness	3
Spinal cord compression	2
Congestive heart failure	1

Complications (Table I)

Bone deformity was present radiologically in 105 patients, being also visible clinically in 33. In 72

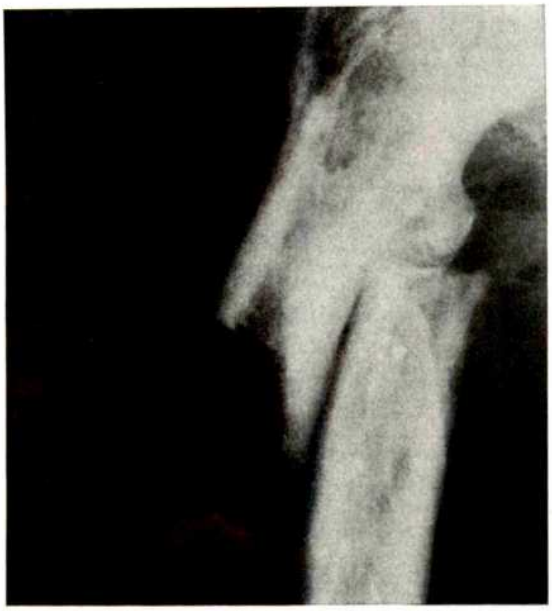

Fig. 1. Typical transverse fracture in the mixed form of Paget's disease. Multiple increment fractures are also visible, represented by transverse radiolucencies on the convexity of the femoral shaft.

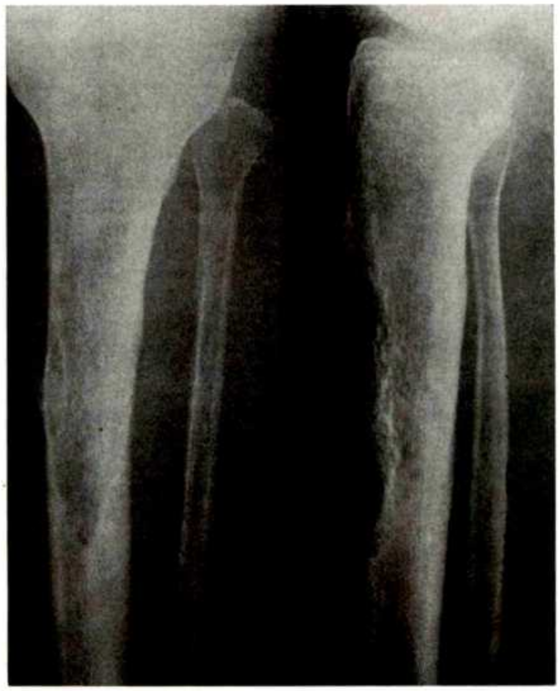

Fig. 2. Paget's disease of the osteoporotic type in the midshaft of the tibia, presenting as a painless swelling. When localized thus, it may be called 'osteoporosis circumscripta'; the sharp lower margin is typical.

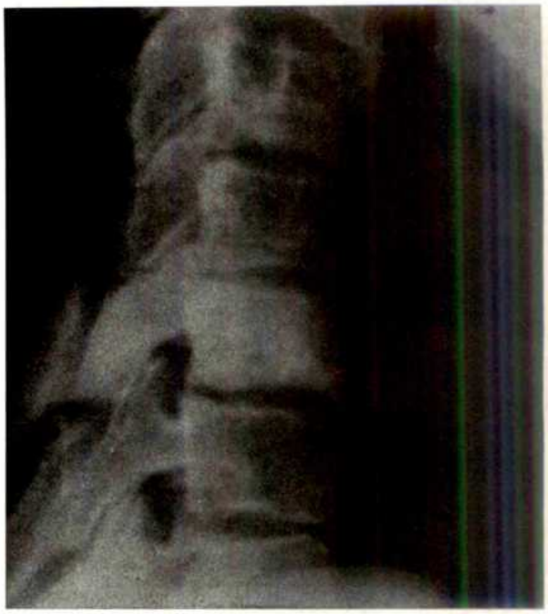

Fig. 3. Sclerosis of C5 vertebra due to the amorphous form of Paget's disease. Involvement of the appendages is characteristic.

patients the deformity was only detected radiologically. Twenty-four of these had basilar invagination, which was found in one-third of those with skull involvement. This is diagnosed when a line drawn from the posterior end of the hard palate to the undersurface of the occiput cuts the odontoid peg more than 6 mm below its apex (McGregor's modification of Chamberlain's line). Forty-eight patients had protusio acetabuli, which was present in varying degrees in 10 per cent of patients with pelvic involvement. Wedging of Pagetoid vertebrae occurred in 39 patients. Evidence of disc degeneration also was visible in films of the lumbar spine in 94 per cent of the 400 patients; 11 per cent had spinal osteoporosis and 2 per cent had secondary deposits. One patient had a fracture of the odontoid peg when the second cervical vertebra was involved by the Paget's disease. In 19 patients, 5 of whom had full skeletal surveys, involvement of a single lumbar vertebra was the only evidence of the disease.

Pathological fracture through Pagetoid bone occurred in 24 patients (*Fig.* 1), being a presenting feature in 22 of these. There were 15 femoral fractures (8 transcervical or transtrochanteric, 2 subtrochanteric and 5 femoral shaft). There were 3 fractures of the humerus, 2 of the tibia and 1 each of the ulna, the odontoid peg, the patella and the pubic rami. Eighteen of the fractures occurred in the mixed form of the disease, 1 in the sclerotic form and the remaining 5 in the osteoporotic form. Only 2 patients had any symptoms before the fracture and 1 of these also had visible Pagetoid deformity. Increment fractures (incomplete fractures, generally on the convexity of long bones) (*Fig.* 1) were present in 13 patients, but none of these patients had any related symptoms.

Sacroiliac joint fusion was visible in 15 patients and partial obliteration of the joints appeared to be present in a further 75 patients. In a few of the latter, oblique

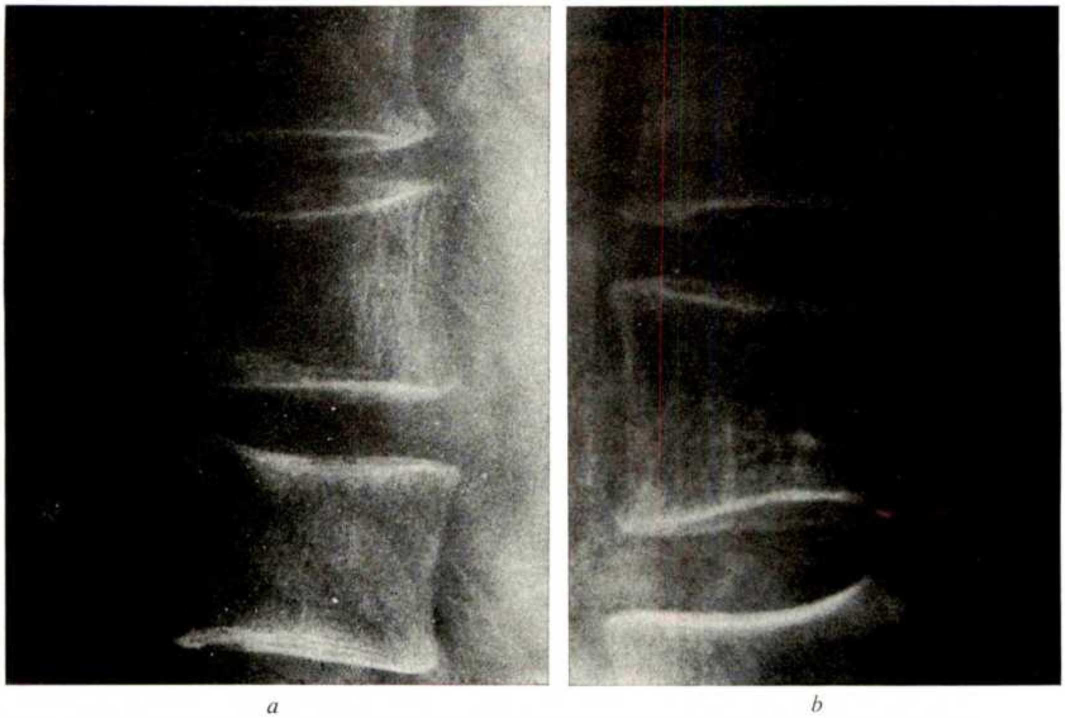

Fig. 4. Osteoporotic Paget's disease of a vertebral body (*a*) with characteristic trabeculation parallel to the vertebral margins, contrasted with the predominantly vertical trabeculation of a haemangioma (*b*).

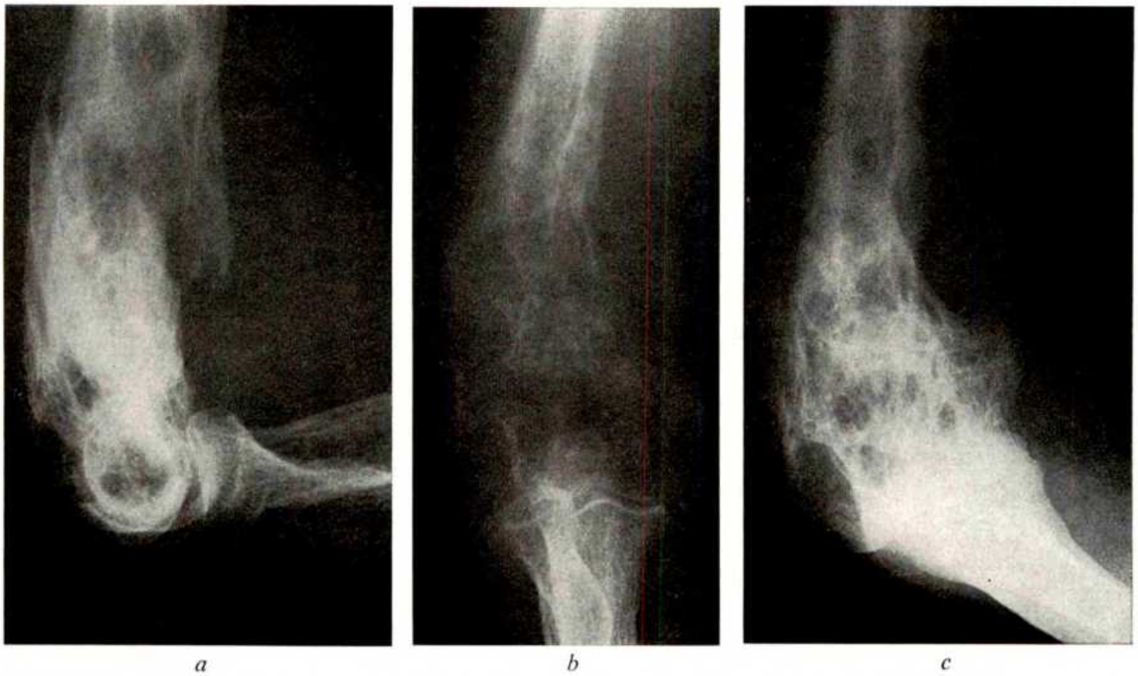

Fig. 5. Fracture in Paget's disease of the mixed form affecting the humerus (*a*), followed by extreme rarefaction associated with immobilization during the acute phase (*b*); this might suggest malignancy were not the initial film available. Final complete healing (*c*).

views indicated that in these the fusion was apparent rather than real.

Three patients had deafness attributed to the Paget's disease. There were no patients with evidence of other cranial nerve involvement. One patient with basilar invagination had evidence of spinal cord compression, and another patient had spinal cord compression due to involvement of the 12th dorsal vertebra.

In 1 patient congestive heart failure was attributed to the bone disease.

Five patients had malignancy complicating their Paget's disease (osteosarcoma in 3, fibrosarcoma in 2); we had no patient with chondrosarcoma or giant cell tumour. In 1 patient with each type of malignancy it was multicentric; in 1 patient the sacrum was involved and in the other 2 patients the femur was affected.

Ureteric colic occurred in 12 patients, and in 5 of these calculi were seen. This frequency of colic is ten times that in the general population (Barker, 1977).

Joint changes were noted in 420 hips of 300 patients with Paget's disease on one or both sides of the hip joint. In 28 hip joints, joint narrowing to less than 3 mm was the only abnormality, and in 330 hips there was evidence of minimal joint degeneration accompanied by a similar degree of joint narrowing. More advanced changes were present in 27 hips.

Frequency of symptoms

In 137 of 361 patients (34 per cent) in whom the disease was reported radiologically, clinicians attributed symptoms to the bone disease (*Table II*). With the exception of the 30 patients who presented with bone pain and the 12 patients who were investigated on account of a raised plasma alkaline phosphatase, all the other patients presented with one of the complications that have already been listed in *Table I*. Painless deformity of bone was the most common presentation (33 patients); 24 presented with pain in joints that were later found to have adjacent Paget's disease, but as will be seen from the discussion below, these symptoms could be coincidental.

Onset and duration of the disease

Thirteen patients were under the age of 55 years at the onset of symptoms; the youngest was a male aged 24 years. Eighteen patients were under the age of 55 at diagnosis. The youngest of these was a male aged 32, and he presented with spinal cord compression due to involvement of the 12th dorsal vertebra. Most patients were aged between 55 and 84, but 11 patients were aged 85 or more. Ten patients have been under observation for between 1 and 20 years with Paget's disease that has so far remained asymptomatic.

Discussion

Clinical suspicion of Paget's disease

The infrequency with which Paget's disease is mentioned on X-ray request cards suggests that clinicians rarely consider Paget's disease as an explanation of symptoms before its radiological detection. In no patient was Paget's disease mentioned on the request card unless the diagnosis had been previously established, or there was clinical deformity, or the patient was being investigated for a raised plasma alkaline phosphatase. Failure to report radiologically visible Paget's disease could be due to a failure of observation or to the consideration that it was irrelevant to the clinical problem.

Table II: CLINICAL SYMPTOMS OR SIGNS AT PRESENTATION IN 137 PATIENTS WITH PAGET'S DISEASE

Bone pain	30
Osteoarthritis	24
Deformity	33
Fracture	22
Malignancy	5
Low back pain	10
Spinal cord compression	1
Raised plasma alkaline phosphatase	12

Symptoms and complications of Paget's disease

Amongst the 105 patients with bone deformity, there were 33 in whom the condition was visible both clinically and radiologically but who were otherwise symptom-free; this is considerably less than the incidence of visible deformity in other series—36 of 116 patients described by Gütman and Kasabach (1936) and 52 of 111 patients recorded by Rosenkrantz et al. (1952). One of the 24 patients with basilar invagination had pressure upon the spinal cord at the foramen magnum.

Of 39 patients with vertebral wedging, only 1 had symptoms attributed to this by clinicians, although 9 others had low back pain. Dickson et al. (1945) state that symptoms are common with this finding, but Barry (1969) considers that it is doubtful whether Paget's disease in the spine ever gives rise to symptoms. He suggests that loss of vertebral height in Paget's disease should be considered a deformity rather than a fracture. The difficulty in ascribing symptoms to Paget's disease of the spine is also indicated by the frequency with which disc degeneration is present, and there was frequently no reason given for attributing pain to Paget's disease rather than to the disc degeneration in this series of patients. Involvement of a single vertebra by sclerotic Paget's disease (*Fig.* 3) may give rise to difficulties in diagnosis, when sclerotic deposits from breast or prostate, bone infection, benign osteoblastoma, lymphoma and osteoid osteoma may all have to be considered and bone biopsy may have to be undertaken (Fairbank, 1951; Brailsford, 1954; Schwartz and Rebeck, 1954; Dennis, 1961; Finby and Begg, 1963). When the osteoporotic form of the disease affects the spine (*Fig.* 4), haemangioma of vertebra is the main differential diagnosis.

Pathological fracture occurred in 22 of the patients at presentation, and as a later complication in a further 2 patients, often following minimal trauma. There were only 2 subtrochanteric fractures of the femur, which Barry (1969) claims to be the commonest site. Five fractures occurred owing to the osteoporotic form of the disease (Grainger and Laws, 1957). This frequency of pathological fracture is only half that of other series (Newman, 1946; Rosenkrantz et al., 1952), probably due to different patient selection in these series. Extreme rarefaction, which may occur in the region of such fractures due to the combination of immobilization and the already pathological bone, occurred in 1 patient (*Fig.* 5), simulating malignancy. In 13 patients there were increment fractures, but none of these patients appeared to have symptoms. Allen and John (1937) suggest that these fractures may become complete, which may have occurred in the patient illustrated in *Fig.* 1. Barry (1969) considers that these result from repeated minor trauma; in no patient in this series with this complication were there recognized episodes of bone injury.

Sacroiliac joint fusion in 15 patients appeared to be complete, and was seen when both sides of the sacroiliac joint were affected by Paget's disease. In no patient was there any history, or pain, to indicate inflammatory sacroileitis, and the cause of this appearance is uncertain; cartilage necrosis similar to that in the hip joint (Campbell-Golding, 1971) may play a part.

Authenticated cases of cranial nerve involvement by Paget's disease do seem to be rare (Kay et al., 1934; Dickson et al., 1945; de Deuxchaines et al., 1964), and the best description of involvement of the orbital nerves was given over 50 years ago (Wyllie, 1923). The relation of deafness to Paget's disease affecting the skull is not clear (Newman, 1946; Clemis et al., 1967; Prestanick, 1969; Nager, 1975). It appears that the mixed sensori-neural deafness could equally well be due to otosclerosis or arteriosclerosis, and current methods of testing do not differentiate. Narrowing of the internal auditory meatuses is rarely demonstrable. The commonest neurological complication is spinal cord compression (Turner, 1940; Latimer et al., 1953; Klenerman, 1966; Cartlidge et al., 1972). Headache is likely to be coincidental (Kay et al., 1934).

Congestive heart failure was common, but in only 1 patient in the series was it attributed to Paget's disease, and even here the extent of skeletal involvement was considerably less than the 30 per cent which is normally considered necessary to cause haemodynamic upsets (Clinicopathological Conference, *British Medical Journal* (1965), pp. 803–6). Well-documented cases of heart failure due to Paget's disease are rare (Alpert, 1958; Harrison; 1958), but a hyperdynamic circulation is common. Both are attributed to increased blood flow through the diseased bone, which may be twenty times normal (Edholm et al., 1945). Other complications, such as valvular and myocardial calcification and peripheral vascular disease, are probably no more common in Paget's disease than in the general population (de Deuxchaines et al., 1964; Guyer and Dewbury, 1978).

There were 5 patients with malignant change and if, as Galbraith (1954) suggests, only 10 per cent of patients in the community who have Paget's disease are seen in hospital, then the frequency of this complication is certainly less than 1 per cent (a figure suggested by Price and Goldie (1962) and Barry (1969)), and is probably in the region of 0·1 per cent. In 28 per cent of patients aged 55 years or more who have bone sarcoma, osteitis deformans is considered to be a predisposing factor (Coley and Sharp, 1931).

Ureteric colic occurred in 12 patients (3 per cent of the series). Slightly greater frequencies of this complication are recorded by Dickson et al. (1945), Newman (1946), Snapper (1949), Rosenkrantz et al. (1952) and Ridlon (1962). Barker et al. (1977) have found an incidence for urinary calculi of 20·7 per 100 000 admissions per annum. The prevalence for this complication amongst the Southampton patients suggests that it is ten times as common in Paget's disease as it is in the general population. Hypercalcaemia and hypercalcuria are known to occur in Paget's disease, particularly at times of inactivity (Goldstein and Abehouse, 1935), but there was no evidence of inactivity in the patients of the present series who had colic.

Graham and Harris (1971), Roper (1971) and Detenbeck et al. (1973) have all expressed difficulty in ascribing joint degeneration and joint symptoms to Paget's disease, the first of these authors stating that symptoms are rare. In a study comparing 300 patients with Paget's disease adjacent to the hip joint (Guyer and Dewbury, 1978) it was concluded that Paget's disease does not predispose to osteoarthrosis but gives rise to specific joint abnormalities, i.e. narrowing of joint space and protusio acetabuli.

Pain associated with Paget's disease

There were 30 patients in whom radiologically detected Paget's disease of bone was used to explain localized bone pain (*Table II*). The pain as described in these patients was of variable severity, of a deep, boring nature and rather constant, being unrelated to joint movement. Less severe pain could be controlled by oral analgesics; more severe pain was regarded as an indication for calcitonin therapy, to which it generally responded if the patient tolerated, and persevered with, the injections. All the patients developing malignancy presented with pain of increasing severity associated with swelling around the malignancy; none of them had had any symptoms before the onset of the pain, which was attributed to the malignant change.

Age of onset of symptoms

The onset of symptoms in 13 patients under the age of 55, and the actual diagnosis of the disease in 18 patients in the same age range, emphasize the fact that Paget's disease is not solely a disease of advancing years. Paget's seventh patient was aged 28, and there are many patients of similar age reported in the literature (Roberts and Cohen, 1926; Kay et al., 1934; Gutman and Kasabach, 1936; Brailsford, 1938; Fairbank, 1951; Seaman, 1951; Collins, 1956; de Deuxchaines et al., 1964). The youngest fully documented patient in the literature is 18 years of age (Wagner, 1947).

Conclusions

If the 24 patients with osteoarthrosis and the 12 with an asymptomatic elevation of the plasma alkaline phosphatase are excluded, there remain 101 out of 361 patients (28 per cent of those in whom a clinical reaction can be judged) who appear to have symptoms attributed to their Paget's disease by their clinicians. This is in keeping with the suggestion, made both by Galbraith (1954) and Collins (1956), that approximately 20 per cent of patients have symptoms attributable to their bone disease, but it must be remembered that in some of those with pain there was no clear reason for attributing this to Paget's disease rather than disc degeneration for example. This is probably offset to an unknown extent by patients who had symptoms due to Paget's disease but which were not recognized as such.

Taking the symptoms and complications together, it is recommended that, apart from those patients who present with complications of their Paget's disease, the condition should continue to be recorded in the notes and reported to the general practitioner when discovered incidentally during radiological examinations, because it may from time to time lead to an explanation of symptoms or to an alteration in diagnosis and management. When initially revealed radiologically, Paget's disease may well be of significance in relation to bone pain, spinal cord compression, ureteric colic, fracture and malignant change; it is not likely to be significant in patients with low back pain, osteoarthrosis, heart failure, headache and cranial nerve palsies. There is evidence that Paget's disease is a progressive process (Guyer and Clough, 1978), so that even though the disease may be asymptomatic on presentation, it may later become symptomatic.

On survival rates in surgical treatment for ischaemic leg

Sir,

I find it difficult to see how Dr Boba's interpretation of our findings (*Br. J. Surg.* 66, 293) differs from our own. We also consider that our results give no cause for optimism. Few vascular surgeons consider the long term fate of their patients with anything but pessimism. We have presented the data in an attempt to help each surgeon assess 'whether the early risks of surgery and the late risks of death from general causes . . . warrant salvage surgery'.

I suspect that most surgeons will be unable to follow Dr Boba's concept that a force '. . . tends to displace the individual from a condition of being alive to one of being dead . . . .' In practice, we find that death is a precise event. However, if a colloquial analogy is that we are all dying slowly and the vascular patient is dying rather more quickly, then the concept is hardly remarkable.

I do not understand why Dr Boba presents 'alternative conclusions', for they are identical to our own, though worded very differently. Certainly, the presence of clinical atherosclerosis and its treatment worsen survival rates. The operations discussed are designed to save the leg, not the patient. Certainly, amputation is the easy way out, and may well involve the least physical trauma though at the expense of psychological distress and a considerable burden on relatives and the community. In the discussion, we stressed that the results should not influence the choice of operation.

Dr Boba presumably does not understand that a successful salvage operation allows far quicker ambulation than does amputation. Finally, it goes without saying that vascular surgeons advise appropriate changes in lifestyle as part of general management.

Anterior highly selective vagotomy

Sir,

We have read with great interest the article by Messrs Hill and Barker entitled: 'Anterior highly selective vagotomy with posterior truncal vagotomy: a simple technique for denervation of the parietal cell mass' (*Br. J. Surg.* 65, 702–705). For some time we have been performing anterior highly selective vagotomy with posterior truncal or selective vagotomy in an attempt to preserve an adequate blood supply to the lesser curve of the stomach. Anterior highly selective vagotomy with posterior selective or truncal vagotomy has been performed in 4 patients with uncomplicated duodenal ulcer. The diagnosis was confirmed at the operation. There were 3 males and 1 female of mean age 31 years. In 2 cases we have performed anterior highly selective vagotomy with posterior selective vagotomy and in 2 cases, anterior highly selective vagotomy with posterior truncal vagotomy.

Two weeks after the operation the mean percentage reduction of basal acid secretion was 71 per cent and maximal, after histamine, was 55 per cent. Hollander's test was negative. The reduction of acid secretion achieved after this type of vagotomy is very similar to results after highly selective vagotomy in our patients (mean reduction of BAO, 75 per cent; MAO, 50 per cent).

Of our 103 cases of highly selective vagotomy, ischaemic necrosis of mucus membrane of the lesser curve occurred in 2. Necrosis was confirmed by gastrofibreoptic examination and subsided after medical treatment. Therefore, we carried out an investigation on the blood supply to the lesser curve of the stomach after highly selective vagotomy. In conclusion, we think that the only way of preventing ischaemic necrosis of the lesser curve after highly selective vagotomy is by performing anterior highly selective vagotomy and posterior truncal or selective vagotomy. The vessels of the posterior leaf of the gastrohepatic ligament ensure blood supply to the lesser curve of the stomach.

In our patients operated in this way the gastrofibreoptic picture of the mucus membrane of the lesser curve in the early stage (3 days) after the operation was normal. Gastric secretion (basal and maximal) decreased in a similar manner to that seen by Hill and Barker. The Hollander test was negative. Gastric emptying as assessed by radiological examination in the early stage after operation was not delayed.

If the late results of this kind of vagotomy are as good as those after highly selective vagotomy, it seems that this modification may prevent necrosis of the lesser curve of the stomach.

Book reviews

An Introduction to the Symptoms and Signs of Surgical Disease

Norman Browse. 245 × 185 mm. Pp. 409+viii. Illustrated. 1978. Edward Arnold: London. £12·75.

THE author's declared intention in producing this book has been to emphasize to our medical undergraduates the need to acquire proper techniques in clinical skills such as history-taking and clinical examination. There is no doubt in my mind that he has achieved this main objective, as the book consists of a simple, clear and well-structured account of this rather loosely defined subject. In addition, the text contains a considerable amount of essential core knowledge relevant to clinical practice, together with revision panels which should be of considerable help to the student and the newly qualified houseman.

Occasionally, I did find the text to be too dogmatic when it need not have been so, and I am sure that not everybody would agree with all its statements. Nevertheless, this is inevitable, as clinical practice must always relate in the end to the individual practitioner. It does, however, reflect in the main the general consensus of opinion and the book should be strongly recommended to undergraduates. Perhaps the book would gain by the inclusion of some colour illustrations, but no doubt this would add further to the cost, which at the present level of £12·75 is probably already on the expensive side for the average student.

A. CUSCHIERI

Reanimation of the Paralyzed Face. New Approaches

Edited Leonard R. Rubin. 280 × 210 mm. Pp. 367. Illustrated. 1977. St Louis: Mosby. No price given.

TEN years ago the treatment of the paralysed face was relatively simple but there has been a plethora of new techniques, including microsurgery, which has altered the picture. This book describes many of the techniques simply and well. It discusses their relative merits and disadvantages without bias. They all have some drawbacks and further developments and refinements are expected.

The presentation is good. Each chapter is succinct and starts with a short summary. The book is well illustrated, both by line drawings and by monochrome photographs; there is a very useful bibliography. There are nine contributors, most are from North America, but included are the pioneers of microneural repair from Europe, Millesi and Anderl. The microvascular work is covered by Harii and Ohmori from Japan. As well as plastic surgeons, neurologists, ENT surgeons, a pathologist and a specialist in rehabilitation have written chapters.

The book is divided into four parts. Part One covers the anatomy and the physiology of nerve and muscle damage; Part Two the causes of facial paralysis; Part Three the techniques of free nerve and muscle grafting, and the largest section, Part Four, the actual management of cases, both immediate and after months and years.

The book should be read by all who have an interest in this field and my only reservation is that some of the older techniques are abandoned. For instance, the static sling, it is said, 'should not be used under any circumstances'. Hypoglossal facial anastomosis is only briefly mentioned. Tarsorrhaphy is not discussed, nor does the editor approve of weights, magnets or slings around the eye. There is no mention of the help that rhytidectomy can give to the late case. Yet this is a book on 'new approaches' and this topic is covered well.

B. MORGAN

A Course in Renal Disease

Geoffrey M. Berlyne. Fifth edition. 215 × 140 mm. Pp. 450+x. Illustrated. 1978. Oxford: Blackwell Scientific. £6·75.

THE fact that this book is now in its fifth edition in 1978 having been first published in 1966 speaks for its popularity. The book is designed to sustain the reader's interest by posing questions at frequent intervals. The scope of the text is wide and once the basic anatomy and physiology have been covered then more detailed nephrological topics are discussed. There is no doubt that this volume has greater value for the physician than the surgeon, but nevertheless the sections dealing with physiology, hypertension, acute renal failure, therapeutics and specific surgical diseases of the kidney will be of undoubted interest and value to the surgeon.

This volume cannot be described as essential for the private surgical bookshelf, although its presence in the library would be beneficial as certain topics are presented clearly and in a fashion that holds the reader's attention.

F. THOMPSON

A Simple Guide to Trauma

R. L. Huckstep. Second edition. 190 × 120 mm. Pp. 250. Illustrated. 1978. Churchill Livingstone: Edinburgh. £2·95.

SIMPLE is the word for this excellent little book. As an aide-mémoire for students of medicine, nursing and allied disciplines, it is almost unbeatable and there can be few more experienced practitioners who will not find something of value within it. If I have any criticism, it is of the format. The ring binding is deplorable and I feel that Professor Huckstep has in this respect, and this respect only, been rather let down by his publishers, but doubtless they will remedy the matter when the third edition comes along, as indeed it must.

J. G. P. WILLIAMS

Malignant Diseases of Infancy, Childhood and Adolescence

Arnold Altman and Allen D. Schwartz. 255 × 175 mm. Pp. 531+x. Illustrated. 1978. Eastbourne: Holt–Saunders. £20·00.

THE eighteenth volume in the series *Major Problems in Clinical Paediatrics* is devoted to malignant diseases of infancy, childhood and adolescence. Edited by two paediatric haematologist–oncologists, it is directed primarily at the practising general paediatrician who is confronted only rarely with this potentially lethal condition. The major emphasis is on the diagnosis of malignancy and on the recognition and treatment of life-threatening complications. The natural history and prognosis of the various conditions are delineated. The treatment of malignant disease is becoming increasingly complex and demands the establishment of specialized regional centres with multidisciplinary cooperation. The authors wisely omitted details of many treatment protocols that have not become firmly established and limit their discussion to those regimens which are fairly standardized and successful. The sections on oncologic emergencies and on the psychological and social support of the patient and family are particularly relevant to the primary physicians and equally instructive for the multidisciplinary team engaged in the acute management and long term care. The text is well written and concise and the references are comprehensive and up to date. The book is modestly priced by present standards. I would strongly recommend it for all those individual specialists engaged in the management of children with malignant disease despite the fact that surgical management is only briefly discussed.

LEWIS SPITZ

Scoliosis and Other Spinal Deformities

John H. Moe, Robert B. Winter, David S. Bradford and John E. Lonstein. 270×190 mm. Pp. 691+xix. Illustrated. 1978. Eastbourne: Holt–Saunders. £21·00.

THIS book is an outstanding contribution to the practice of spinal surgery. The four authors constitute the staff of the famous Twin Cities Scoliosis Centre at Minneapolis which has done much to pave the way in the surgical management of spinal deformities. This publication documents their views after 25 years' experience.

The introductory part includes detailed and useful chapters on patient evaluation, the normal development of the spine, and the natural history of untreated spinal deformities during childhood and adult life. The different types of scoliosis from the common idiopathic curve to that seen in association with Marfan's syndrome are then considered. There is a valuable contribution on the spinal deformities in myelomeningocele which reflects the relatively large numbers of adolescent spina bifida patients being seen at present. After sections on Scheuermann's kyphosis and adult scoliosis there is a series of shorter chapters on spinal infection, trauma and the deformities seen in the different types of dwarfism.

The emphasis throughout the book is on the practical management of these conditions, and in particular space is given to the details of surgical methods and possible complications. Techniques in plaster casting and brace orthotics are described thoroughly.

Just as Professor J. I. P. James's book on scoliosis has become the standard reference of the resident training in spinal surgery, this volume must have a similar role for the consultant specializing in the treatment of spinal deformities. One minor criticism which arises when one compares these two works concerns the Minneapolis book's dismissal of the aetiology of idiopathic scoliosis in one paragraph.

This publication is a 'must' for the book shelves of orthopaedic, thoracic and neuro- surgeons concerned with spinal deformities, where, before long, it will undoubtedly become a well-thumbed classic.

M. EDGAR

General Urology

D. R. Smith. Ninth edition. 260×180 mm. Pp. 541+ix. Illustrated. 1978. Los Altos: Lange. $14.50.

THIS is a new edition of a well-established textbook intended for medical students and junior hospital doctors. There is plenty of information in the book, but little discussion on the surgical aspects of treatment; for instance, the techniques of prostatectomy occupy less than half a column, and retropubic prostatectomy is discussed in three lines. Postoperative management is omitted.

There are good sections on the newer types of investigations, such as renography, renal scanning, ultrasound and CT scanning, but modern urodynamic techniques are dismissed as being too esoteric. The quality of X-ray reproduction is not satisfactory, including one X-ray being upside down. This book is competing against other good urological textbooks and I rather fear that its pages will remain unturned in the average medical school library.

P. H. L. WORTH

Critical Resection Length and Gap Distance in Peripheral Nerves

G. Orf. 230×155 mm. Pp. 91+viii, with 45 illustrations. 1978. Berlin: Springer-Verlag. No price given.

THIS monograph describes the results of stretching the sciatic nerves of 56 giant rabbits and reviews the relevant literature. From the results the critical resection length for these nerves was determined. This is the length which limits direct end-to-end suture. It appears that the length is about 3 per cent.

The book will be of interest to surgeons concentrating on the peripheral nervous system, and to thesis writers, for whom it is exemplary.

M. WATSON

Vascular Trauma

Norman M. Rich and Frank C. Spencer. 265×190 mm. Pp. 610+xiv. Illustrated. 1978. Eastbourne: Holt–Saunders. £27·00.

NOWHERE more than in military surgery is it true that progress is by rediscovery. History tells the same story at intervals down the years. From Ambroise Paré to the large company of vascular surgeons who served in Viet Nam this great, definitive book at last sets these lessons in clear and rational order. Colonel Rich and Dr Spencer, both distinguished in their specialty, have at one time set out the landmarks, stated the aphorisms and shown the way ahead. They give tribute to the 600 young American surgeons whose careful work and clear records during the stressful years 1965–72 provided the data in thousands of arterial repair operations, with a striking and even success rate that more than anything proved the soundness of the principles learned in the earlier conflict in Korea.

In this book there is no padding. All the space is filled with useful facts, demonstrations and advice. From the vast mass of information in this memorable text a reviewer can only draw what he feels to be a few good examples of this helpful style of authorship: such as the incidence of anatomical anomaly of the popliteal, the widely differing operative tactics for coeliac and superior mesenteric injuries, nerve involvement in a false aneurysm and the fine colour plate of a contused, intact but occluded brachial. The text itself is clear and easy to read. It is fine testimony to much magnificent effort.

H. H. G. EASTCOTT

1978 Year Book of Surgery

Edited Seymour I. Schwartz et al. 200×135 mm. Pp. 550. Illustrated. 1978. New York: Year Book (London: Lloyd–Luke). £18·50.

MOST readers will be familiar with this series and the 1978 edition lives up to the high standard of previous volumes. The layout and print are excellent with illustrations, X-rays and charts clearly reproduced so that the book is a pleasure to read. There is an opening chapter reviewing most of the recent advances in surgery of the year and the rest of the book is well arranged in chapters according to anatomical site, with a large section on the different aspects of cardiac surgery.

Like all publications of abstracts of papers it is somewhat indigestible with so much information in a relatively short book. However, one of the most valuable features of the book is the comment by the editor at the end of each chapter. These are nearly always helpful, often critical and sometimes acid, but they do add to the balance of the book and the reader finds himself full of admiration for the knowledge and erudition shown by the editors in presenting and criticizing these papers.

H. E. LOCKHART-MUMMERY

Pheochromocytoma

W. M. Manger and R. W. Gifford jun. 265×190 mm. Pp. 398+xxiv, with 132 illustrations. 1977. Berlin: Springer-Verlag. DM113.10; US $49.80.

PHAEOCHROMOCYTOMA is a rare tumour, but is well described in the literature. However, this is probably the first monograph to be devoted to this subject exclusively, and the authors, both physicians with special experience of hypertension, are to be congratulated on a superb work. They describe and discuss all aspects in a systematic, thorough and clear manner, providing a comprehensive list of over 1000 references, and they draw on their own experience, particularly of the use of measurements of catecholamines in the plasma for the diagnosis and localization of tumours.

The sections on anaesthesia and operative removal of phaeochromocytomas are inevitably derived from the experience of others and they would have been more authoritative and helpful if they had been written by an anaesthetist and a surgeon.

Nevertheless this is a very valuable reference book which all medical libraries should possess and which individuals with a special interest in the subject will wish to buy.

R. B. WELBOURN

Operative Surgery

General Editors C. Rob and R. Smith.

Neonatal Surgery

P. P. Rickham, James Lister and Irene M. Irving. Second edition. 245×180 mm. Pp. 621+xii. Illustrated. 1978. London: Butterworths. £42·50.

THE first edition of this excellent book was published in 1969 as by P. P. Rickham and J. H. Johnston. The latter author has not been excluded! As might be expected, he contributes an admirable urological section. The three authors now named are in fact the main contributors of a total of twenty from Liverpool and Zurich. The book is encyclopaedic in the best sense of the word. The first eight chapters are on general subjects, including the ethics of neonatal surgery and the organization of a regional neonatal surgical service, as well as the customary clinical aspects, which are thoroughly covered. The remainder of the book deals with paediatric surgery in a systematic fashion including the cardiovascular system. Historical, embryological and aetiological aspects are covered before the clinical picture, investigation and management. Operations are mostly described in less detail. Each chapter gives the results obtained in the clinics in Liverpool or Zurich. The style of writing is commendably clear, and surprisingly uniform for a multi-author book, and is well up to date. In management, precise instructions are given. The references are full (but surely it is time the old howler of Wyllie G. G. and Adelaide M. B. as co-authors in the *Lancet* 1957 article referred to on p. 455 was laid to rest).

It is inevitable that in detailed contributions such as these there will be some areas of disagreement. The section on Hirschsprung's disease comments on Ehrenpreis's hypothesis that the muscle of the aganglionic section is the seat of denervation hypersensitivity (p. 422), whereas the work of Garrett and Howard and others suggests that the abnormal extensions of the preganglionic fibres into the muscle layers make effective contacts. Nor would I consider the risk of formal rectal biopsy any less than that of suction biopsy which can be applied with so much less disturbance of a possibly sick newborn, although I agree that neither technique is entirely free of risk in practice. Also it is presumably an oversight that the stress of asphyxial birth is not included in the list of risk factors which should lead to particularly careful observation for early signs of necrotizing enterocolitis. But these are relatively trivial matters in a book which must become the standard reference text on the subject for years to come.

H. H. NIXON

Loss and Grief in Medicine

Peter Speck. 198×128 mm. Pp. 175+xiii, with 3 illustrations. 1978. London: Baillière Tindall. £2·95.

THIS book is a very timely publication. It comprehensively discusses the management of death and grief in medicine and is easy and interesting to read. Loss and grief are subjects that rarely find a place in surgical journals. This is reflected in the bibliography of the book which contains a noticeably small proportion of references to medical and surgical as opposed to nursing and behavioural journals and monographs. The book describes the surgical situations in which loss followed by grief may occur—amputation, mastectomy, colostomy etc. It describes how grief may be anticipated and understood, how long grief lasts and the role of doctors and nurses in its management.

For me the last section of the book, which dealt with different religious and ethnic reactions to grief, was most illuminating. We now live and work in a multi-racial society and it is imperative that surgeons know the cultural impact that operations may have and what rituals must be attended to when a patient, who is not a member of one of the long-established indigenous religions, dies. The author must be congratulated on producing a compact and informative book which can confidently be recommended to all who practise the art and craft of surgery.

H. BRENDAN DEVLIN

Metabolic Surgery

Henry Buchwald and Richard L. Varco. 235×155 mm. Pp. 317, with 57 illustrations. 1978. New York: Grune & Stratton. No price given.

THIS book is composed of a series of review chapters dealing with a variety of topics related to surgery, each by an author eminently qualified to discuss his own particular field. The overall title of the book, *Metabolic Surgery*, is perhaps a little misleading as the book includes chapters that would seem to describe types of surgery with relatively few metabolic implications. For example, there is a chapter about the spleen which describes features of the haematological and oncological significance of that organ rather than any particular metabolic aspect. However, the authors may feel that the inevitable metabolic changes associated with any form of surgery should imply that almost any surgical topic might be included under this particular title.

It is useful to see reviews in the same book on theoretical and practical aspects, together with the results of management of difficult surgical problems such as obesity by means of gastric and ileal bypass. There is also a comprehensive discussion of the place of intestinal bypass and portacaval shunting in the management of the hyperlipidaemias and glycogen storage diseases.

A number of the chapters hold a particular interest because their topics are unfamiliar in most surgical texts, the chapters on the role of pulsing electromagnetic fields and functional neurosurgery being noteworthy.

In conclusion, although the title of this book is a little misleading, the contents include a number of excellent reviews of current surgical topics which are worth further study.

P. D. WRIGHT

Carcinoma of the Oesophagus: Proceedings of the First South African Conference on Carcinoma of the Oesophagus, Cape Town

Edited W. Silber. 235×155 mm. Pp. 474+xi. Illustrated. 1978. Rotterdam: Balkema. £21·00.

THIS book records the proceedings of the First South African Conference on Carcinoma of the Oesophagus, held in Cape Town in January 1977. As would be expected in view of the site of the conference and the very high incidence of oesophageal cancer in the native population of South Africa, especially in the Transkei, the majority of the speakers came from South Africa, but the programme also included papers from known experts in this subject from Europe, Japan and North America. The early sessions of the conference were devoted to the epidemiology of the condition, with excellent accounts of the widely varying incidence of this condition in different parts of the world and of its apparent increase in the Transkei in recent years, together with discussion of the possible aetiological factors. The major portion of the conference was concerned with the clinical and pathological features of the disease, its diagnosis and the difficult problems of its treatment, problems often exacerbated in Black patients in South Africa by severe malnutrition and concomitant pulmonary tuberculosis. Various papers report the results of radiotherapy and surgical excision in several large series of patients, and there are interesting accounts of treatment plans involving both these modalities, sometimes combined with chemotherapy, together with the use of the various types of intubation, either during the course of attempted curative treatment or as the principal method of restoring swallowing in those patients in whom cure is impossible.

This book covers all aspects of the problems presented by this terrible disease and it is undoubtedly a mine of information. Its value is enhanced by the extensive references included at the end of most of the contributions. The book suffers, however, from the fact that it is apparently a verbatim record of the conference, and its value would have been greatly increased by careful pruning and editing. This is not a book for the general surgical reader, but rather for the specialist with a particular interest in this condition, who will certainly find in its pages much to interest him.

L. P. LE QUESNE

Clinical Anatomy of the Heart

Robert Walmsley and Hamish Watson. 245 × 191 mm. Pp. 229. Illustrated. 1978. Edinburgh: Churchill Livingstone. £22·50.

In this book the authors set out to bring the traditional anatomical descriptions of the isolated heart into a more realistic clinical and radiological perspective. It follows the familiar lines of an anatomical text backed up by numerous radiographs and vertical and transverse whole body sections. No allowance is made for alterations in the anatomical relationships with age, posture, stature, obesity, respiration and cardiac hypertrophy.

In the first chapter there is an abbreviated description of the embryology of the heart, which would be insufficient for the primary fellowships: it omits a description of separation of the truncus and explanation of the common congenital abnormalities met in surgery—Fallot's tetralogy, transposition of the great arteries etc.

Some of the illustrations are not very clear and others might be interpreted differently—the X-ray *Fig.* 1.39 on p. 47 looks more like a pneumonectomy than a lobectomy. Most surgeons would agree that the oesophagus may be indented by the left main bronchus as shown in *Figs.* 4.1, 4.2 and 6.12, yet *Fig.* 4.13 attributes the indentation to the right main bronchus. There is little place for schematic drawings in an anatomical text (*Fig.* 9.11). Other illustrations show a degree of artistic licence which could be misleading, e.g. the left coronary artery in *Fig.* 4.5. The text uses a number of archaic anatomical terms, e.g. 'margo acutus' and 'brachiocephalic artery', and generally lacks clinical familiarity; for instance, why call it the 'anterior descending (interventricular) artery' when most of us know it as the left anterior descending or just LAD.

The description of the fibrous skeleton of the heart is useful, but needs to be tied up with surgical experience at valve replacement and in the preparation of homograft valves. The descriptions of the coronary arteries and conductive tissue are insufficient for the clinical needs of surgeons, e.g. how to avoid putting a stitch in the bundle while closing a VSD or replacing an aortic valve or in the coronary sinus while replacing a mitral.

As John Kirklin says in the foreword, this book has provided some important clinical material. To my mind it will be of use to anatomists and pathologists for occasional reference, but I cannot see it being kept readily at hand in the wards, or in the operating theatre, and least of all on the clinician's own desk or bedside table and, after all, 'clinical' means 'at the bedside'.

J. W. JACKSON

Surgical Pediatric Urology

Edited H. B. Eckstein, R. Hohenfellner and D. I. Williams. 295 × 225 mm. Pp. 533+ix, with 1120 illustrations. 1977. Eastbourne: Holt–Saunders. £66·25.

The three editors of this book have for the first time attempted a comprehensive review of the operations currently in use for all the commonly encountered urological disorders of childhood. To assist them in this task they have assembled a team of distinguished contributors from Europe and America, each writing upon a subject of which he or she has made a particular study. The result is a magnificent volume, a work of major importance in the field of paediatric urology.

The book is aimed at those who have already acquired the basic surgical skills and who either intended to pursue a career in paediatric urology or who wish to develop a deeper interest in the subject, although the editors are careful to stress that some of the procedures described should only be attempted by those who have access to the full back-up services provided by a modern paediatric specialist centre.

Throughout, the emphasis is on operative technique, the intention being that the work should be complementary to the standard paediatric urological textbooks which will provide more complete clinical and diagnostic detail. Despite this, there is an excellent first section which reviews the available diagnostic techniques and discusses overall surgical management. This includes chapters on nursing care, anaesthesia and oncology as well as outstanding contributions on paediatric nephrology and imaging.

As befits a textbook of operative surgery, illustrations are used extensively to clarify the steps of the individual operations. Here the editors have been fortunate in their choice of Rudolf Brammer, who has illustrated the book throughout and has produced more than a thousand drawings of outstanding quality. These are used to particular effect in the chapters dealing with ureteric reimplantation, pyeloplasty and hypospadias repair where a number of alternative techniques have to be described, although the orientation of some of the drawings of intra-abdominal procedures is at times confusing.

The approach to some problems and the spelling and use of some words (as, for instance, in the chapter on testicular tumours) may make English readers a little uncomfortable, but such vagaries are hardly surprising in a work which is aimed at an international readership. Generally all interests are well catered for and there are detailed chapters on haemodialysis and transplantation as well as an unusually long section on urinary tract trauma. Most of the authors have followed their operative descriptions by brief comments on postoperative care and the management of possible complications, whilst at the end of the volume there is an elegant chapter which discusses the long term results of the various procedures.

The choice of print and the layout of the text make the book easy to read, whilst the binding is properly substantial and should withstand repeated handling.

This beautifully produced volume achieves all its aims. The price is high, but nevertheless it represents excellent value for money.

R. MORGAN

MGH Textbook of Emergency Medicine

Edited Earle W. Wilkins. 260 × 180 mm. Pp. 829+xviii. Illustrated. 1978. Baltimore: Williams & Wilkins. No price given.

This massive book is the joint work of sixty-two contributors, all of whom are part of the Emergency Medical Services of the Massachusetts General Hospital. The organizational skills required to achieve this synthesis are of themselves to be admired and much of the content is admirable. The production is superb and the line drawings, like so many in texts from the United States, are in the direct line of Max Brödel with a clarity and directness that it is impossible to fault. As a reference source it will be difficult to improve upon. And yet if one really wants to know what to do, and when, the text is often less than helpful. To be told 'that fiberoptic esophagogastroscopy and selective endoscopy are major recent contributions to the management of profuse gastrointestinal bleeding', but not to be told when to use these investigations and in what degrees of bleeding is frustrating. Many of the statements encountered are empty, for example: 'the mounting availability of selective angiography not only for diagnosis but also for therapy has given the physician a new option and . . . has caused a shift of emphasis away from immediate surgical treatment'. But what options; how has the emphasis shifted; how does it influence the way the next case should be handled? These things we are not told. Similarly in the relatively short section on abdominal trauma, peritoneal lavage (as distinct from tap) is not mentioned; truisms appear such as 'a patient with a traumatic abdominal injury [*sic*] should be closely attended at all times and if his condition deteriorates he should be treated promptly—by laparotomy if necessary'; and we are told that 'radionuclide scanning and arteriographic examination may be useful in patients in whom the diagnosis is suspect', but we are given no idea when these investigations are used.

A skilled craftsman is rightly a little suspicious of multipurpose tools: they usually do all the tasks a little less well than specialized single-use instruments. I have the same feeling about this book. Having edited a similar, though more limited volume in the emergency field myself, I know the difficulties of marshalling disparate facts and opinions. However, in this area, as in no other, direct practical advice is vital, but unfortunately there is little of it here.

QUESTIONS AND ANSWERS IN GENERAL SURGERY

H. P. HENDERSON, FRCS, *Senior Registrar, Plastic and Jaw Surgery, Fulwood Hospital, Sheffield;* and M. J. KELLY, MChir, FRCS, MRCP, *Senior Registrar in General Surgery, Bristol Royal Infirmary*

With a Foreword by The Right Hon. the Lord Smith of Marlow, KBE, MS, FRCS

This book contains questions and answers suitable for candidates revising for the Final FRCS Examination in General Surgery. The whole field for the examination is covered including subspecialties. The questions are laid out in random fashion to lessen the tedium of learning section by section and the answers have been placed adjacent to the questions. An index has been provided to enable readers to work through particular sections of their revision if they so wish

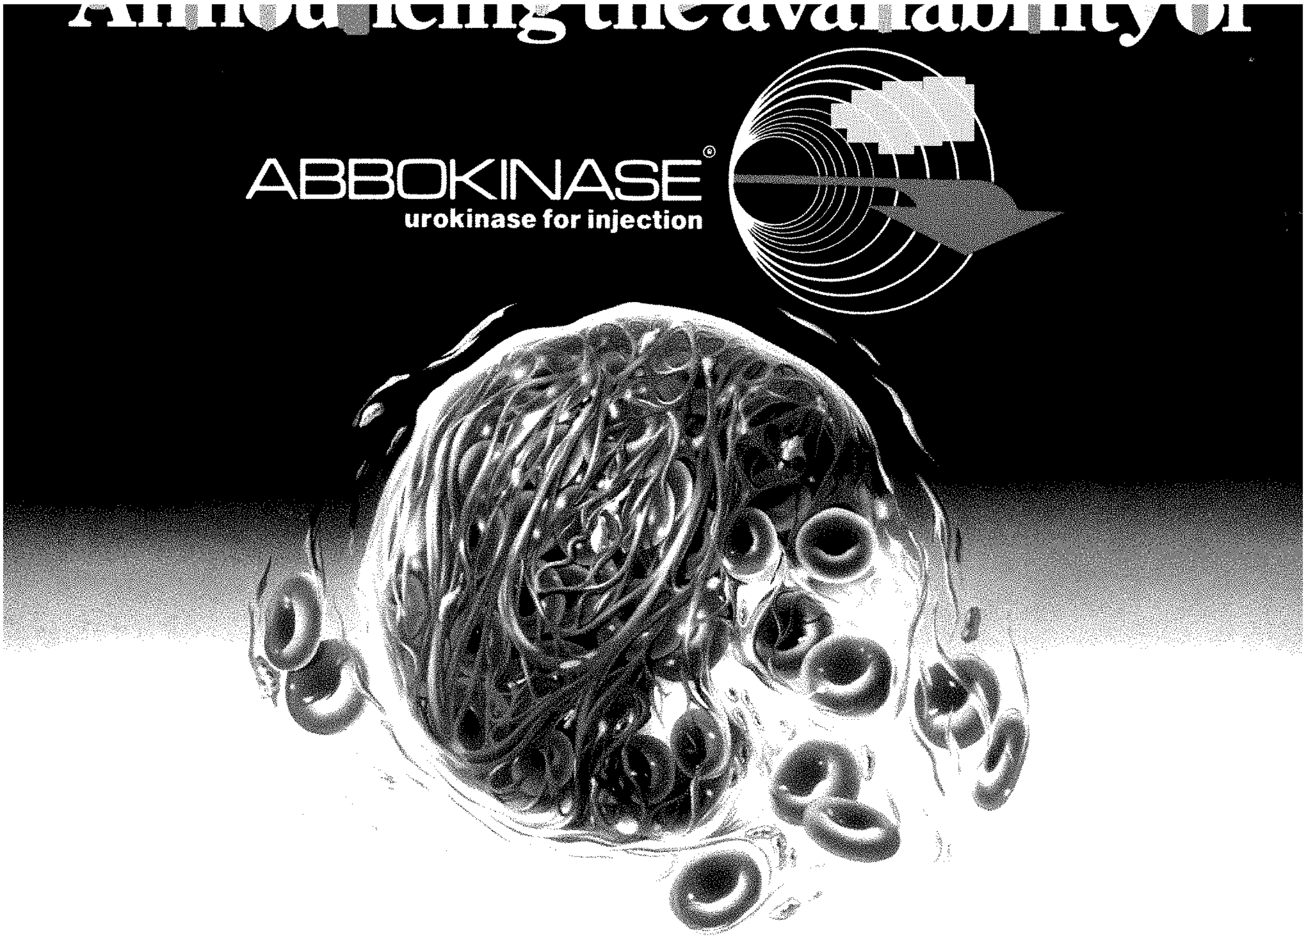
ISTOL



The first tissue-culture urokinase for the treatment of pulmonary embolism.

With significant advantages, both clinical and practical, over other thrombolytics, anticoagulant therapy and surgery.

- **Abbokinase achieves rapid clot lysis by a direct action on the fibrinolytic mechanism. Urokinase has a greater affinity for plasminogen within the formed clot (gel phase plasminogen) than for circulating plasminogen (sol phase plasminogen)[1] and is therefore the most selective thrombolytic agent in current use.[2]**
- **Abbokinase is devoid of antigenic activity in humans – unlike streptokinase. This obviates prior antibody testing and the need for corticosteroids for the prevention and alleviation of allergic response.[3]**
- **Abbokinase is more successful than anticoagulants which do not lyse the clot or reopen the vessel.[4,5]**
- **Abbokinase is more economical and less traumatic than surgery.**

ata sheet information **Presentation** Abbokinase is available in 10ml vials containing 250,000iu of a highly purified sterile lyophilised formulation of urokinase obtained from cultures of human kidney cells. Urokinase is a lasminogen activator excreted in the urine of normal healthy individuals When reconstituted with 5.2ml distilled water according to directions, each ml of isotonic solution will contain 50,000iu urokinase, 5mg mannitol and mg sodium chloride **Uses** Abbokinase in vivo and in vitro produces the release of plasmin by an enzymatic action on human plasminogen Abbokinase has only minimal activity in reducing fibrinogen levels but blood lasminogen levels are reduced, the effect being dose-dependent Abbokinase is virtually non-antigenic to humans and, in therapeutic doses, is thromboplastin-free Thrombolytic therapy is indicated in the treatment of ascular occlusions caused by forming or recently formed fibrin clots Theoretically the best results will be obtained with thrombi less than 24 hours old. Abbokinase is indicated as a thrombolytic agent in pulmonary mbolism. **Dosage and Administration** Abbokinase is administered intravenously by continuous infusion, usually for a period of 12 hours. It is recommended that Abbokinase be given in a solution of Normal Saline by constant fusion. An initial loading dose to be given during the first ten minutes of therapy is advocated This loading dose should be equal to the amount which it is planned to administer over each succeeding period of one hour Ideally, n infusion pump should be used to maintain a constant rate of infusion. Abbokinase is reconstituted with 5.2ml sterile water for injection, without preservatives For administration the reconstituted solution should be further luted with normal saline to the total volume of solution (195ml) for a 12 hour treatment including the priming dose From this solution, 15ml are given over a period of 10 minutes as the priming dose and the remainder over a eriod of 12 hours at the rate of 15ml/hour Dosage. It should be noted that patient-to-patient variation in response can be expected, due to individual variation in levels on inhibitory factors Certain disease states such as aemia, some malignancies and dyslipidaemias can be associated with an increased plasma level of urokinase or plasmin inhibitors. In other conditions such as massive pulmonary embolism, endogenous fibrinolytic ctivity may be increased. The recommended dosage regimen for the treatment of pulmonary embolism is Loading dose 4,400iu per kg bodyweight over 10 minutes Constant infusion dose 4,400iu per kg bodyweight per our Duration of infusion 12 hours **Contra-indications, Warnings, etc.** Contra-indications. Manifest or recent (i.e. within 3 days) haemorrhage. Any haemorrhagic diathesis. Severe hypertension; During cardiopulmonary suscitation, During pregnancy or suspected pregnancy. Warnings and Precautions. The major adverse effect of Abbokinase is haemorrhage, usually associated with too high dosage A high incidence of bleeding from inor skin lesions, therapeutic and diagnostic puncture sites and pre-existing gastro-intestinal lesions has been observed with high dosages Any evidence of significant internal bleeding necessitates the cessation of rombolytic therapy. An anti-fibrinolytic agent such as epsilonaminocaproic acid (EACA) may be used as an antidote if required Epsilonaminocaproic acid should be available for use, if necessary, during infusions with bokinase when high doses are being administered Post-partum for one month Recent surgery (within 3 days) Concurrent anti-coagulant therapy should be administered cautiously. Mild mperature increases have been observed during thrombolytic therapy with Abbokinase. When there is a history of hypersensitivity to drugs etc., caution is advised and facilities as well as rticosteroids, adrenaline, etc should be readily available when Abbokinase is infused Monitoring. The monitoring of fibrinolytic activity and of plasminogen levels is desirable Pharmaceutical ecautions The lyophilised powder should be stored at 2-8°C Reconstituted solution should be used immediately after mixing and secondary dilution **Legal Category** POM **Package Quantities** ailable in packs of 2 vials of 250,000iu each (List No. 6109) **Further Information** The potency of Abbokinase is expressed in International Units (iu) For practical purposes the iu is considered by most thorities to be equivalent to the CTA unit The Ploug unit is usually considered to be equal to 1.4iu. **Product Licence Number** 0037/0096. **References** 1 Kakkar VV, Scully M F Thrombolytic therapy *Brit ed. Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, John Wright & Sons Ltd, Broadmead House, 21 Panton Street, London SW1Y 4DR.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the journal unless rights are reserved before publication.

Business communications should be sent to *John Wright & Sons Ltd, British Journal of Surgery, Bristol BS8 1EX.* Remittances are payable to the *British Journal of Surgery.*

Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

Manuscripts

The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations

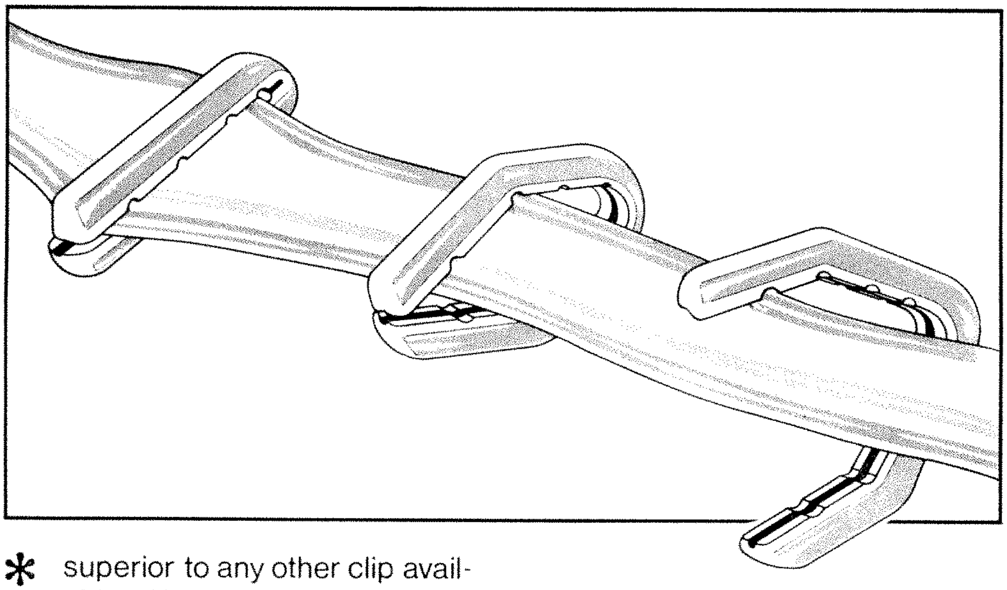
It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978: **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors.* London, Pitman, 1978.

References

In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus.* Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).

Weck® Hemoclip®

Surgical occlusion proven in over 12 years' use



- ✱ superior to any other clip available will not slip off blood vessel; allows partial occlusion if necessary
- ✱ routinely used in more than 40 different surgical procedures
- ✱ pre-formed to direct pressure uniformly in the applier-true parallel closure without scissoring
- ✱ distal end closes first to encompass all the vessel
- ✱ available in four sizes

Hemoclip closure:
Left is the clip closed, providing a tenacious yet hypotraumatic grip.
Centre is the partially closed clip forming a ring. Right is the open clip; magnifying the longitudinal and transverse grooving-a milled, grooved surface that grips securely without slippage.

SEEING OPERATIVE SURGERY

by

F. T. GRAVES AND D. GRAVES

This book will fascinate any surgeon. After describing the basic principles of surgery and offering guidance on practicalities such as pre-operative care and liaison with theatre staff, the author deals with 46 surgical procedures ranging from tying knots with one hand to an abdomino-perineal excision of the rectum. The outstanding feature of the book, however, is its 492 photographs whose unparalleled quality offer a unique insight into the surgeon's art.

ETHIBOND* Polybutylate Coated Braided Polyester

The suture for the specialist:

Polybutylate is the first agent developed specifically for coating suture material. As only a minimal amount of this new coating is required to reduce tissue drag, the soft pliable characteristics of the polyester yarn are not impaired. The illustration shows a laboratory simulation of a technique in which braided polyester is drawn through a controlled 'bubble' of polybutylate ensuring an even application of the coating.

ETHIBOND Sutures provide the exceptional tensile strength and the smooth passage through tissue that is required in specialist areas of surgery—such as cardiac and vascular procedures.

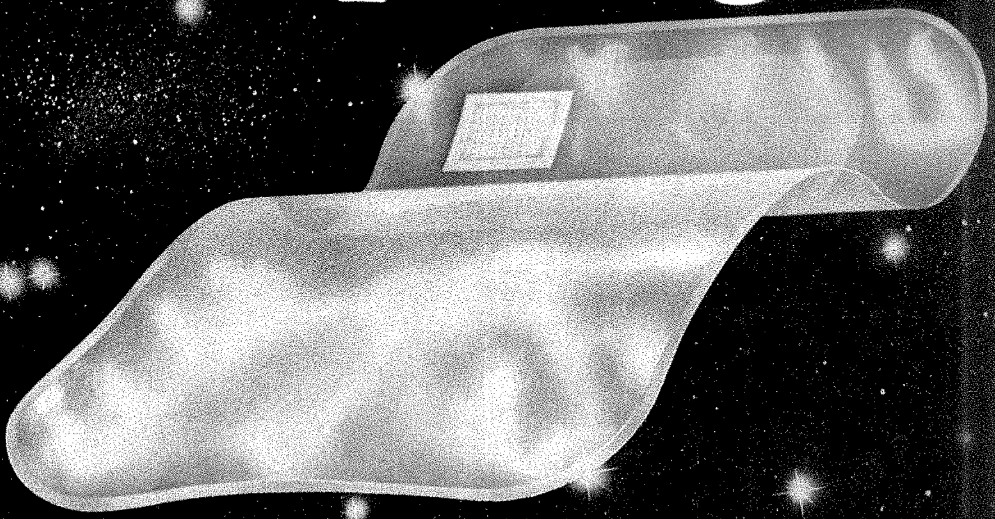
Hollister conquers gas



At last - a highly effective flatus filter from Hollister

No leaks, no odour — Hollister have made sure that this new deodorising flatus filter is really effective and trouble-free.

Every colostomy patient knows the discomfort and embarrassment that occurs when a stoma bag swells up with flatus. Now Hollister have developed a flatus filter system that solves this problem successfully. Laboratory trials have proved its reliability.

Gas is released automatically through the unique Hollister* deodorising filter — packed with thousands of tiny odour-trapping granules of activated charcoal.

No leaky filter, no odour, no more discomfort or embarrassment. It really works. Hollister have conquered gas!

Another major advance from The Team That Cares

Benign Breast Disorders

3 studies on Danol

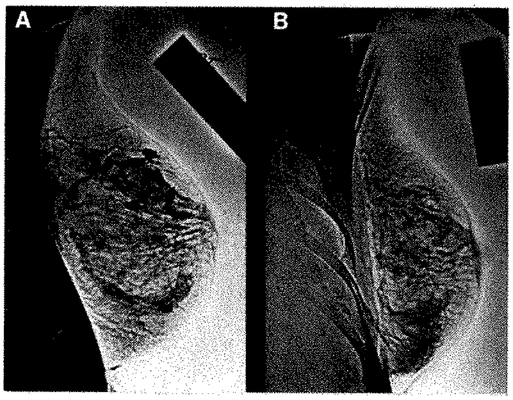
1. "...a marked improvement in both objective and subjective symptoms in 87.5% of patients studied."

(Study of 40 patients given Danol for up to 6 months. Obstet. Gynec. 1976, 48: 93.)

---

2. 75.8% "...experienced complete relief of subjective discomfort with disappearance of clinical signs."

(Study of 58 patients given Danol for between 74 and 310 days. Am. J. Obstet. Gynec. 1977, 127: 130.)



Xeromammograms of patient with intense fibrocystic disease (A) showing marked reduction in breast size and cystic area (B) after 6 months on Danol.

---

3. "...a significant decrease and elimination of breast pain and tenderness ...and elimination of nodules and lumpy areas..."

(Preliminary report on open study of 260 patients given Danol for 4 to 6 months. J. int. med. Res. 1977, 5 (Suppl. 3) 101-108.)

Danol
danazol

antigonadotrophic agent without oestrogenic or progestogenic activity

Danol (danazol 200 mg) PL 0071/0095. Bottles of 100 capsules. Basic NHS cost of one day's treatment £1.42 (3 capsules). **Danol-½** (danazol 100 mg) PL 0071/0094. Bottles of 100 capsules. Basic NHS cost of one day's treatment 72p (3 capsules). **Dosage** Adults 200-800 mg daily. See Data Sheet for details. **Contra-indications** Pregnancy. **Precautions** 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop. **Side Effects** Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control. Danol is a trade mark. Set – 0 407 00632 X *£90.00* *US $202.50*

This Third Edition of *Orthopaedics* reflects the expansion in orthopaedic surgical procedures as the emphasis has shifted from pure surgical craft to applied science. Although the important classic procedures have been retained, almost all chapters have been rewritten, incorporating new sections on such developing areas as total joint replacements, internal and external fixation of fractures, arthroscopy, operations for spinal deformities in children and surgical treatment of haemophilia. The multidisciplinary background of modern orthopaedics is illustrated in chapters on the principles of repair and replacement of injured musculo-skeletal tissues, spinal injuries and treatment of orthopaedic diseases.

These volumes cater not only for the needs of the orthopaedic trainee, but will also prove invaluable to the consultant orthopaedic surgeon and to the general surgeon with less experience in this field.

Distribution of plasma-bound hydroxyproline in breast cancer, benign breast disease and healthy females

M. F. NEHLAWI, A. CUSCHIERI, J. CLARK AND R. A. B. WOOD[*]

SUMMARY

In normal adult females, patients with benign breast disease and patients with breast cancer, hydroxyproline (OHPro) was found in the plasma attached to the protein fractions which were separated by Sephadex gel filtration. In addition, a distinct moiety, probably a protein sub-unit, containing substantial amounts of this imino acid, occurred in between gel filtration fractions III and IV. Quantitative differences in the OHPro content of these various fractions were observed in the groups of patients studied. Significant elevations in the peptide-bound OHPro (fraction IV) were found only in patients with breast cancer and the level appeared to correlate with the degree of advancement of the disease. Similar findings relate to the OHPro content of the sub-protein moiety which is found between gel filtration fractions III and IV. A reduced level of high molecular weight hyproprotein (fraction I) was found in the breast cancer group.

URINARY hydroxyproline (OHPro) determination has been used as a sensitive index of collagen metabolism in human tissue (Prockop, 1963). Excretion of this imino acid is elevated in a number of disease states particularly in disorders of connective tissue, skin and the endocrine system (Ziff et al., 1956; Benoit et al., 1963; Brunish and Sørensen, 1965). An increased excretion of urinary OHPro is also encountered in primary and secondary tumours of bone (Platt et al., 1964). In 1973 Cuschieri reported that urinary OHPro was persistently elevated in patients with breast cancer who subsequently developed osseous deposits and this was later confirmed by Powles et al. (1975) and Roberts et al. (1975).

Plasma OHPro is found in the free and bound forms. The presence of dialysable OHPro-containing peptides in normal plasma has been previously reported (Prockop et al., 1962; Smiley and Ziff, 1964). In addition, there is a form of OHPro which is non-dialysable and protein-bound and which is released by acid or alkaline hydrolysis (Le Roy et al., 1964). The latter has been referred to as hyproprotein or collagen-like protein as it is resistant to hydrolysis by pronase and chymotrypsin. Increased levels of hyproprotein(s) have been reported in a variety of clinical states (Le Roy and Sjoerdsma, 1965). This study was undertaken to investigate the distribution of peptide- and protein-bound OHPro in the plasma of patients with benign breast disease and patients with early and advanced breast cancer.

Patients and methods

Included in the study were 32 patients with histologically proved breast cancer, 14 patients with benign breast disease (fibroadenosis, cystic mastopathy, fibroadenoma) and 24 adult healthy females who were the control group.

On the basis of our method of staging, the breast cancer group was subdivided into 15 with early disease (group A) and 17 with advanced cancer (group B). Patients in group A had no evidence of dissemination and either no histological axillary node involvement or a maximum of two lymph nodes involved. The advanced breast cancer group had either evidence of metastatic spread or advanced locoregional disease with extensive axillary node involvement, defined as three or more ipsilateral axillary nodes with tumour deposits on histological examination.

The assessment of patients with breast cancer included clinical examination, mammography, aspiration needle cytology with subsequent frozen-section histology, technetium-99^{m} sulphacolloid liver scan, liver function tests (serum albumin, total protein, bilirubin, alkaline phosphatase, aspartate transaminase, gamma-glutamyl transpeptidase and prothrombin time), laparoscopy, technetium-99^{m} methylene diphosphonate bone scan, chest X-ray and X-ray of the lumbosacral spine and pelvis. Hot areas on the isotope bone scan were further investigated by radiology, and areas of increased uptake of the isotope were interpreted as deposits only if the X-ray films of the region showed no evidence of benign disease or trauma.

Both patients and control subjects were put on a gelatin-free diet for 2 days. The blood samples for OHPro studies were taken at the end of this period. None of the patients or controls admitted to the study had any concurrent disease known to affect the turnover of collagen and the excretion of OHPro in the urine. Blood was collected in EDTA for the estimation of plasma OHPro. The plasma was separated and stored at −20 °C until required.

The procedure of Le Roy et al. (1964) was modified for the estimation of plasma-bound OHPro. One millilitre of plasma and 4·0 ml of ethanol were mixed and the solution was left to stand at room temperature for 15 min. It was then centrifuged at 2127 *g* for 10 min. The protein residue was separated from the ethanol layer.

To the protein precipitate, 2·0 ml 12 M HCl were added and the mixture was hydrolysed at 120 °C and 12 psi, for 18 h. The hydrolysate was evaporated to dryness and then dissolved in 1·5 ml of distilled water. One millilitre of the mixture was transferred to the cation-exchange chromatography column. The eluate solution was collected, neutralized, evaporated to dryness and then dissolved in 1·0 ml distilled water. Grant's method (1964) was used to measure OHPro.

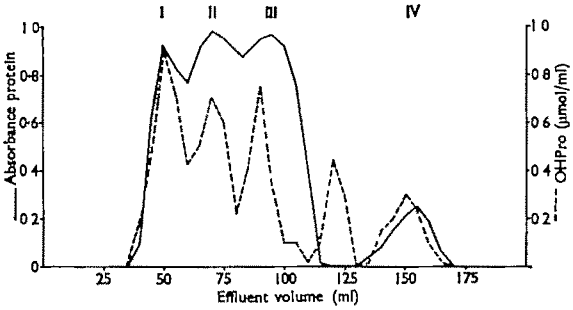

Fig. 1. Hydroxyproline (OHPro) in protein fractions from plasma of healthy female volunteers.

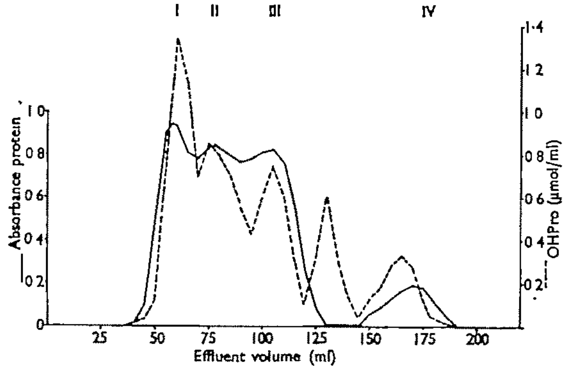

Fig. 2. Hydroxyproline (OHPro) in protein fractions from plasma of patients with early breast cancer (group A).

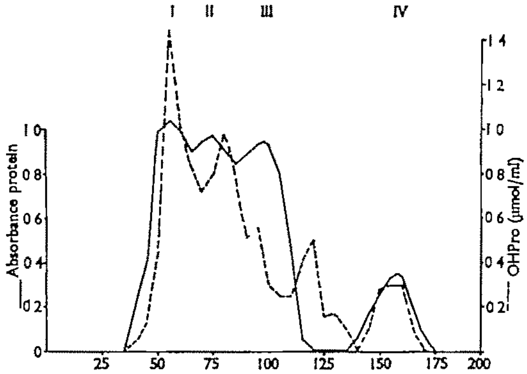

Fig. 3. Hydroxyproline (OHPro) in protein fractions from plasma of patients with advanced breast cancer (group B).

Plasma proteins were fractionated using a Sephadex G200 gel filtration. The column height was 90 cm and its diameter 1·5 cm. Four-millilitre plasma samples were run in a buffer containing 0·154 M NaCl and 0·01 M Tris at pH 8·0. Sodium azide (0·02 per cent) was added to the solution to avoid bacterial growth. A flow rate of 4·0 ml/h was adopted (bed volume, 135 ml). Fractions of 5·0 ml each were collected for about 36 h in an automated fraction collector (LKB). The proteins were measured by UV absorption at 280 nm. Two millilitres of 12 M HCl were added to 4·0 ml of each protein fraction, hydrolysis was then performed and this was followed by cation-exchange chromatography. The OHPro content of each fraction was then measured.

Statistical analysis

As the data obtained were not of a normal distribution, all statistical comparisons were carried out by non-parametric analysis using the rank sum test.

Results

The total bound OHPro (peptide and protein) in the plasma (*Table I*) was significantly elevated in patients with breast cancer compared with healthy controls and patients with benign breast disease. In general, the high levels were obtained in patients with advanced disease (group B). However, the wide scatter of these results did not allow any effective discrimination between breast cancer and the other groups.

The protein content of the various gel filtration fractions is shown in *Table II*. Minor differences from control values were found in both patients with benign breast disease and patients with breast cancer but there was considerable overlap between the various groups. Small but significant elevations of the protein content of fraction I were observed in both patients with benign breast disease and patients with early breast cancer (group A). A reduced protein content of fraction III was found in patients with breast cancer but a greater reduction was observed in the protein content of the same fraction in patients with benign breast disease.

Typical examples of the plasma protein separation patterns and the OHPro content of the various fractions in healthy females, group A and group B breast cancer patients are shown in *Figs*. 1, 2 and 3. The peaks of OHPro and the protein fractions were coincident. However, an additional OHPro peak was found located in between gel filtration fractions III and IV. There was no qualitative difference in either the protein separation or the distribution of OHPro between the various groups. The OHPro content of the various gel filtration fractions is shown in *Table III*.

Group B	17	2·27±0 09**	1·52±0·08	1·80±0·18*	5·60±0·62**

($\bar{X}$±s.e. mean.)
* $P<0{\cdot}025$; ** $P<0\ 005$ (rank sum test).

A marked elevation of the OHPro content of fraction IV (peptide fraction) was observed in patients with breast cancer. The level of this peptide-bound plasma OHPro clearly separated the breast cancer patients from both patients with benign disease and healthy female controls. In addition, the OHPro peak between gel filtration fractions III and IV was significantly elevated only in patients with breast cancer. The OHPro content of both fraction IV and the separate OHPro peak in between fractions III and IV appeared to relate with degree of advancement of the disease. A significant reduction of the OHPro content of fraction I was found in patients with cancer of the breast.

As there were quantitative variations of protein in the various fractions, the specific activity of OHPro in each gel filtration fraction was calculated and expressed as mmol OHPro/g protein. These results are shown in *Table IV* and demonstrate a significant elevation of the specific activity of OHPro in fraction IV and a decreased specific activity in fraction I in patients with cancer of the breast.

Discussion

In addition to the free imino acid, OHPro is found in the human plasma in the peptide-bound form and as a component of certain proteins known as hyproproteins. The high molecular weight hyproprotein which accounts for 55 per cent of the total is eluted from Sephadex columns with the early protein fractions containing the α2-macroglobulins and α- and β-lipoproteins. A smaller later peak of hyproprotein has been recovered from the albumin fraction (Le Roy et al., 1964).

Although the total bound OHPro in the plasma was found to be elevated in patients with breast cancer, there was considerable overlap between the groups studied, including the healthy female controls. There were no qualitative differences from the normal pattern of distribution of OHPro amongst the plasma protein fractions in patients with either benign breast disease or breast cancer.

One of the significant quantitative changes from the normal observed in the breast cancer patients was a reduction of the high molecular weight hyproprotein in fraction I, despite the elevation of the total protein content of this fraction from the plasma of patients with breast cancer. The interpretation of this finding is difficult as both the exact nature and the pathological significance of hyproproteins remain to be determined. The suggestion that they represent collagen released from cells (Le Roy et al., 1964, 1965; Oh et al., 1968) is based on indirect evidence and the chemical identity between hyproprotein(s) and collagen has not been established. Even if they are associated with the metabolism of collagen, hyproproteins constitute a different pool from the peptide-bound OHPro as Le Roy et al. (1965) reported a total lack of correlation between hyproprotein levels and urinary peptide OHPro. Elevated levels of plasma hyproprotein have been found in the acute phase of a variety of disease states such as inflammatory and febrile illnesses, renal disease, rheumatoid arthritis etc. It could be argued that plasma hyproproteins are acute phase reactants akin to C-reactive protein, haptoglobin and pre-albumin. There is some evidence based on animal experiments with C^{14}-proline and a positive correlation between hyproprotein content and IgM levels in humans that the high molecular weight hyproprotein contains the immunoglobulin IgM (Tomaszewski and Kowalewski, 1975).

The plasma peptide-bound OHPro has received very little attention. It accounts for 6–10 per cent of the total OHPro in the plasma of healthy adults. Isotopic studies have shown that peptide-bound OHPro in the urine is derived from the turnover and degradation of both soluble and insoluble collagen (Prockop, 1963). In the present study, a significant elevation of the OHPro content of fraction IV was found only in patients with breast cancer. This gel filtration fraction reflects the polypeptide component of the plasma and its OHPro content is, therefore, in the peptide-bound form. Patients with extensive locoregional disease and/or evidence of spread tended to have higher levels than patients with early breast cancer although there was overlap between these two subgroups. As it is extremely likely that some of the patients assessed as having early disease will have occult spread despite attempts at accurate staging, a valid assessment on the value of plasma peptide-bound OHPro as a prognostic index and as a monitor of disease activity in cancer of the breast can only be based on the subsequent clinical outcome of these patients. We have as yet no definite information on any relation between plasma peptide-bound OHPro and survival in breast cancer as the period of follow-up for the patients included in this study has ranged from 6 months to 2 years.

A distinct peak of OHPro was observed in between gel filtration fractions III and IV. This is likely to represent a protein sub-unit rich in OHPro. A significant increase in this OHPro peak was found in cancer of the breast, especially in patients with advanced disease. Further studies including purification, degradation and high pressure liquid chromatography are being performed in our laboratory to determine the exact nature of this moiety.

Whilst some of the changes reported in this study may simply reflect an increased turnover of collagen by metastatic tumour, their protein nature cannot be fully explained by this simple hypothesis. It seems logical to assume that the increased collagen turnover is not a local tissue response, but a component of a systemic reaction to an advancing neoplastic process characterized by complex changes in the plasma proteins. There is some support for this concept from recent studies in lymphoma patients where an increased excretion of urinary peptide OHPro was found exclusively in patients with systemic manifestations and related closely with pyrexia, elevated ESR and weight loss (Nehlawi et al., 1979).

Midline cancer of the floor of the mouth: role of suprahyoid dissection

ALI A. EL-DOMEIRI*

SUMMARY

Of 37 patients with squamous cell carcinoma of the floor of the mouth seen during a 5-year period, 28 were treated primarily by surgery. Ten of the 28 patients presented with midline cancers measuring between 1·0 and 3 cm (T_1 and T_2). Three of these patients had local excision only. Metastases to the submandibular lymph nodes later occurred in 1 of these 3 patients. The remaining 7 patients with midline lesions had wide excision of the tumour, marginal resection of the mandible and bilateral suprahyoid node dissection. Of these 7 patients 4 remained free of disease for periods ranging between 2 and 5 years. Two of these had lymph node metastases. These results suggest that en bloc excision of relatively small midline cancers (i.e. not exceeding 2 cm (T_1) in largest diameter) with bilateral suprahyoid node dissection gives effective control of these lesions.

SQUAMOUS cell carcinoma of the floor of the mouth arises from a strip of mucosa lining a U-shaped groove between the tongue and alveolar margin. This tumour spreads directly to adjacent structures and, via the lymphatics, to the cervical lymph nodes (Helfrich et al., 1972). Distant metastases are less frequent and occur later. Cancers originating in the anterior part of the floor of the mouth frequently extend across the midline, and hence have the potential to metastasize bilaterally to the regional lymph nodes (Ditrois, 1972). Furthermore these lesions often involve the orifices of Wharton's ducts, which may act as conduits for tumour extension to the submandibular region (Landa and Zarem, 1973).

Patients with cancer of the floor of the mouth who were included in this study were treated primarily by surgery. A conservative surgical approach was adopted in patients with relatively small lesions that originated in the midline and involved both sides of the floor of the mouth.

Patients and methods

Patients

During a 5-year period, 1971–5, a total of 37 patients with squamous cell carcinoma of the floor of the mouth was treated at the University of Illinois and Cook County Hospitals. Thirty-two of these patients were male and 5 female, with ages ranging between 44 and 79 years. Sixteen patients presented with anterior lesions that crossed the midline (*Table I*). Of these 16 patients, 10 with tumours measuring 1–3 cm (T_1 and T_2) which seemed to originate in the midline and involved both sides were considered candidates for a conservative operation. Two of the 10 patients had palpable nodes in the suprahyoid region and 3 presented with unilateral or bilateral swollen submandibular salivary glands.

Methods

Three patients with superficial midline cancers not exceeding 1·5 cm in diameter (T_1) and who had no palpable lymph nodes in the neck were treated by wide local excision through the open mouth. The defect was closed primarily by mobilizing the adjacent mucosa or by split-thickness skin graft.

Table I: STAGE AND LOCATION OF TUMOUR

Stage	Total no.	Crossing midline	Lateral
I (T_1, N_0, M_0)	7	6	1
II (T_2, N_0, M_0)	6	2	4
III (T_3, N_0, M_0; *T_x, N_1, M_0)	11	4	7
IV (T_x, N_{2-3}, M_0; T_x, †N_x, M_1)	13	4	9
Total	37	16	21

* $T_x = T_1$, T_2 or T_3.
† $N_x = N_0$, N_1, N_2 or N_3.

The other 7 patients, with early midline cancers measuring 1·5–3 cm in diameter, had excision of the anterior floor of the mouth, marginal resection of the mandible and bilateral suprahyoid node dissection. A midline lower lip-splitting incision that was extended bilaterally into the submandibular region was utilized (*Figs*. 1–3). Closure of the surgical defect was achieved by mobilizing the mucosa of the lip, cheek and tongue. In 2 patients a second operation was carried out to release the tongue and widen the labiolingual gutter to accommodate a dental prosthesis. In these instances a split-thickness skin graft was used to cover the raw area in the floor of the mouth.

Histological examination of the specimens from each patient revealed that the margins of resection were free of cancer. Of the 7 patients who underwent suprahyoid node dissection, 4 had metastases to the lymph nodes. The number of involved nodes in these patients ranged between 1 and 3.

Treatment of the remaining 27 patients seen during this 5-year period with cancer of the floor of the mouth is shown in *Table II*. Seven patients with advanced disease received radiation therapy or chemotherapy or both. Eighteen patients with lesions confined to one side of the floor of the mouth were treated by resection of the floor of the mouth, part of the mandible and ipsilateral radical neck dissection. Of these 18 patients, 6 with stage III or IV disease received preoperative radiation therapy (5000 rad in 5 weeks). Two other patients with operable tumours were treated by radiation therapy only.

Results

All patients were followed for a minimum period of 2 years (*Table III*). One of the 3 patients who had local excision developed metastases in the submandibular lymph nodes. The other 2 remained free of disease but had persistent swelling of the submandibular salivary glands. These 2 patients had suprahyoid node dissection later in the course of follow-up, mainly to remove the swollen, functionless salivary glands: in neither patient did the removed lymph nodes show metastases. Of the 7 patients who had wide excision of the tumor and suprahyoid node dissection, 4 with T_1 lesions (stage I or III) were free of disease at 2 years. Two of these 4 patients, 1 without clinically palpable nodes, i.e. stage I, and 1 with palpable nodes, i.e. stage III, had histologically proved metastases to lymph nodes in the resected specimen. Recurrent disease developed in the remaining 3 patients who had T_2 lesions (stages II and III). Two patients had local recurrence in the oral cavity and 1 had recurrent disease in the mouth and upper cervical lymph nodes

on one side. One of these 3 patients who received preoperative radiation therapy failed to respond to additional postoperative radiation therapy and chemotherapy. This patient died of the tumour in less than 1 year. The other 2 patients were living with disease during the period of follow-up. Both these patients received radiation therapy and/or chemotherapy. In a comparable group of 11 patients with T_1 and T_2 tumours confined to one side of the floor of the mouth, and who were treated by a resection of the floor of the mouth and the mandible combined with ipsilateral neck dissection (commando operation), 6 were free of disease at 2 years.

Discussion

The chances of curing early cancer of the oral cavity by surgery or irradiation are comparable. In patients with carcinoma of the floor of the mouth control can be achieved with either therapy as initial treatment in two-thirds of patients with stage I and II disease (Flynn et al., 1973). In our series patients with early lesions were treated primarily by surgery. The choice of treatment was influenced by the fact that a large number of these patients were heavy consumers of tobacco and alcohol and exhibited signs of chronic irritation of the oral mucosa. A number of reports indicate that such patients have a greater incidence of oral cancer and are at high risk of developing a second primary (Wynder et al., 1957; Johnston and Ballantyne, 1977). Radiation therapy could possibly increase the carcinogenic effect in these persons (Barton, 1971). Also, cancers of the floor of the mouth frequently involve the alveolar margin and are hidden by the mandible. Radical radiotherapy for these lesions is associated with a significant incidence of osteoradionecrosis (Montana et al., 1969; Hardingham et al., 1977). The incidence of bone necrosis has been reported as notably higher in patients with cancers of the floor of the mouth than in those with other tumours of the oral cavity (Silverman and Chierici, 1965; Barton, 1971).

Approximately 72 per cent of all cancers of the floor of the mouth are found in the anterior part of the gingivolingual sulcus (Mashberg and Meyers, 1976). A significant number of these tumours (29 per cent) have crossed the midline at the time of initial presentation (Helfrich et al., 1972). The incidence of cancers that originated in the midline and equally involved both sides, however, was 7 per cent. Because cancer involving the midline can metastasize bilaterally (Ditrois, 1972; Landa and Zarem, 1973), effective control of these tumours entails eradication of the disease at the primary site and in the vulnerable lymph nodes on both sides of the neck.

The presence of clinically positive nodes or the presence of a lesion whose excision requires a surgical approach that enters the neck are generally accepted criteria for performing radical neck dissection (Harrold, 1971; Spiro and Strong, 1973). The extent of the procedure, with its attendant complications, as well as the low yield of histologically positive nodes in patients who do not have clinically palpable disease, weighs against elective *radical* neck dissection. In this series, suprahyoid node dissection, being an operation of considerably lesser magnitude, was used in the treatment of early midline cancers (T_1 and T_2) to secure a wider margin of resection and remove the lymph nodes and salivary glands that are sites for regional metastases on both sides of the neck. The procedure did not contribute to any significant increase in morbidity or mortality and produced excellent cosmetic and functional results. Marginal resection of the bone preserved the continuity of the mandibular arch and eliminated the disabling deformity that followed removal of the anterior segment of the mandible.

The overall results in patients with midline lesions who had suprahyoid node dissection compared favourably with the results in patients having early lateral lesions treated by a combined resection of the floor of the mouth and ipsilateral neck dissection. Four of 7 patients in the former group and 6 of 11 in the latter group were free of disease at 2 years. The conservative surgical approach for midline lesions was particularly effective in controlling tumours measuring 2 cm or less in diameter (T_1). Also, there were indications that the procedure could have benefited patients with small superficial lesions who were treated by local excision only. In 1 of these 3 patients metastases developed to the submandibular lymph nodes. However, failure of this conservative approach to cure patients with tumours larger than 2 cm indicates that a more radical excision or a combination of therapies should be considered in the treatment of these patients (Leonard and Hass, 1970). Preoperative radiation therapy has been most commonly used as an adjunct to radical surgery, the purpose of irradiation being to eradicate microscopic nests of cells existing beyond the margins of resection, as well as to reduce the bulk of the tumour.

Effective palliation of advanced and recurrent cancers in the anterior floor of the mouth has been accomplished by a combination of chemotherapy and high doses of radiation therapy. Tumours located in the anterior part of the floor of the mouth in particular are more accessible to treatment by intra-arterial chemotherapy infusion (El-Domeiri and Chaudhuri, 1975). A significant reduction of the tumour mass and alleviation of symptoms occurred in some of the patients thus treated.

Acknowledgement

I wish to thank Mrs Laurie Barbour for her help in accumulating data on these patients.

Phaeochromocytomas in 72 patients: clinical and diagnostic features, treatment and long term results

I. M. MODLIN, J. R. FARNDON, A. SHEPHERD, I. D. A. JOHNSTON,
T. L. KENNEDY, D. A. D. MONTGOMERY AND R. B. WELBOURN*

SUMMARY

Phaeochromocytomas were diagnosed in 72 patients in Hammersmith, Belfast and Newcastle between 1955 and 1976. Fourteen were found unexpectedly at autopsy while 58 were diagnosed in life. Associated lesions included neurofibromatosis (7 patients), medullary carcinoma of the thyroid (3), renal artery stenosis (2) and cerebellar haemangioblastoma (1). The clinical features were similar to those reported by others. Hypertension was found in all but one of the patients and was sustained only in 17 per cent, paroxysmal only in 48 per cent and sustained with superadded paroxysms in 33 per cent. Hypertension was significantly greater in the women than in the men.

Diagnosis was confirmed chemically in all patients and urinary vanylmandelic acid (VMA) was elevated in all but one. Tumours were localized correctly by various radiographic techniques and by selective venous sampling in over 80 per cent of patients. The tumours were in adrenals in 59 patients (bilateral in 6) and at extra-adrenal, intra-abdominal sites in 13.

The tumours were removed surgically from those in whom they were diagnosed in life. Before 1967 3 of 17 patients died after operation (18 per cent). Since then patients have been prepared with alpha blockade and have received infusions of plasma, blood or dextran after removal of the tumours. One of 41 patients so treated has died after operation (2 per cent). Phaeochromocytomas were diagnosed and treated in pregnancy in 4 patients, all of whom survived. Two of the fetuses died.

Five tumours diagnosed in life were malignant and 2 recurred (40 per cent). Fifty-three were benign and 2 of these recurred locally (4 per cent).

All but 2 patients (who could not be traced) were followed completely from 1 to 20 years after operation and 3 died during this period. Two-thirds of the patients were alive after 10 years.

Paroxysmal hypertension was abolished by operation, but sustained hypertension often persisted and required drug therapy.

It is concluded that at least one-third of phaeochromocytomas are not diagnosed in life and that a high index of suspicion is required to bring them to light. If they are diagnosed and treated by present methods, the prognosis is good.

IN 1886 Fränkel first described a type of tumour for which Pick (1912) proposed the name phaeochromocytoma. The first complete study of a patient, in whom the diagnosis was made post mortem, was published by L'abbé, Tinel and Doumer in 1922. Four years later Vaquez and Donzelot (1926) recognized the condition during life, and Laubry (1927) treated the same patient with success (at least for 6 months) by irradiation of the adrenals. The first curative surgical removal of a phaeochromocytoma, which had not been diagnosed preoperatively, was reported by C. H. Mayo in 1927. Pincoffs (1929) was the first to recognize the condition preoperatively and then to cure the patient by removal of the tumour. Beer, King and Prinzmetal (1937) first isolated a pressor substance from the blood in such a patient and found that operation abolished the pressor effect. Phaeochromocytomas are now known to secrete adrenaline and noradrenaline in varying proportions (Holton, 1949).

The tumour is rare, but by 1951 Graham was able to review 207 patients from the world literature, and in the past decade several sizeable series have been reported (Sander et al., 1971—21 patients; Öhman et al., 1974—20 patients; ReMine et al., 1974—138 patients; Scott et al., 1976—44 patients; Melicow, 1977—100 patients). In recent years the diagnostic accuracy, localization and treatment have improved greatly (Harrison et al., 1975; Montgomery and Welbourn, 1975; Manger and Gifford, 1977). The long term results of treatment have received little attention and have been reported in only one large series (ReMine et al., 1974). Four of 138 patients died at operation and 128 of the survivors were followed for from 1 to 24 years. Of these, 96 per cent with benign tumours and 44 per cent with malignant lesions survived for 5 years.

The present review concerns a series of 72 patients, seen in three centres, all but two of whom were followed regularly until they died or until the end of the review period, that is from 1 to 20 years. Since many patients with phaeochromocytomas die before they are known to harbour tumours, a special effort was made to discover and include patients in whom the diagnosis was made for the first time at autopsy. Attention has been paid to presenting features, methods of diagnosis and localization, associated conditions, long-term results in patients subjected to operation and analyses of the effects of treatment on survival and on the blood pressure.

Patients

The series includes all patients with tumours diagnosed histologically as phaeochromocytomas in Hammersmith Hospital (in the years 1966–76), the Royal Victoria and City Hospitals, Belfast (1960–75), and the Royal Victoria Infirmary, Newcastle upon Tyne (1955–75). A detailed review of the records and of all surviving patients was made in 1976 and 1977.

The distribution of patients by centre and by whether the tumour was obtained at operation or at autopsy is shown in *Table I*. The numbers in each centre were similar. Fourteen tumours (19 per cent) were found incidentally after death, the highest proportion (35 per cent) being in Belfast.

Montgomery, Royal Victoria Hospital, Belfast. Correspondence to: R. B. Welbourn, Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London.

Clinical features

General: There were 40 male and 32 female patients (*Table I*). The ages at diagnosis were distributed normally (*Table II*), all but 13 patients being between the ages of 20 and 60 years. The youngest was a girl of 9 and the oldest a man of 82.

The duration of symptoms shows a skew distribution (*Table III*), nearly half the patients having a history of less than 1 year at the time of diagnosis. In those whose tumours were found at autopsy the data are inevitably less accurate than in those whose lesions were diagnosed in life. The longest history was 20 years.

No patient gave a family history of phaeochromocytoma.

Twenty major lesions, in addition to phaeochromocytoma, were found in 18 of the patients (*Table IV*). Neurofibromatosis, (10 per cent) (Glushien et al., 1953), medullary carcinoma of the thyroid (Sipple's syndrome, multiple endocrine adenopathy type II) (4 per cent) (Harrison and Thompson, 1975), renal artery stenosis (shown on arteriography on the same side as the tumours) (Melicow, 1977) and cerebellar haemangioblastoma (Chapman and Diaz-Perez, 1962) have all been reported frequently before, but the other conditions (with the possible exception of duodenal ulcer, q.v.) were probably associated by chance.

Patients diagnosed in life: The presenting features in the 58 patients were variable and similar to those reported in other series (*Table V*). Two patients had had previous operations for phaeochromocytomas elsewhere and were referred with local recurrences of their tumours.

Hypertension: A patient was defined as hypertensive if (*a*) the mean of all the systolic or diastolic readings, other than those obtained during hypertensive crises, was greater than the mean for subjects of the same sex and age in the general population (Hamilton et al., 1954), or (*b*) if hypertensive crises were observed and recorded. According to these rigorous criteria, hypertension was present in 57 patients and absent in only 1 (*Table V*, *Figs*. 1 and 2). In 10 (17 per cent) it was sustained, in 28 (48 per cent) it was paroxysmal only and in 19 (33 per cent) it was sustained with superadded paroxysms. One patient, while being hypertensive on occasions, also had *hypo*tensive crises (Ramsay and Langlands, 1962). One of the two patients with apparent renal artery stenosis had paroxysmal hypertension only, while the other had sustained hypertension with superadded paroxysms.

The mean blood pressures for the two sexes and the mean relative blood pressures (i.e. in relation to the means of the general population) show considerable hypertension (*Table VI* and *Figs*. 1 and 2), and the females were appreciably more hypertensive than the males. Two patients, a man of 40 and a woman of 43, had suffered cerebrovascular accidents, with hemiplegia, before their phaeochromocytomas were diagnosed.

Hypertensive retinal changes (Keith et al., 1939) were present in 13 patients: grade I in 4, II in 5, III in 2 and IV in 2.

Paroxysms: Most (50) of the patients complained of 'paroxysms' (*Table V*), the main symptoms being palpitations (41), sweating (30), headache (25), anxiety (20), chest pain (16) and abdominal pain (12). One patient was able to induce paroxysms by rubbing his flank. All paroxysms were probably accompanied by hypertensive crises, but these were actually observed in only 47 patients.

Metabolic disturbances: Nine patients had overt diabetes, abnormal glucose tolerance curves or glycosuria. One required treatment with insulin, two with oral hypoglycaemic agents and one with diet alone. The others did not receive any special treatment.

Three patients had hypercalcaemia without any cause, other than phaeochromocytoma, being found (Gray and Gillon, 1976).

Haematuria: Two patients with phaeochromocytomas in the bladder had haematuria. One also had paroxysmal giddiness on micturition.

Pregnancy: Phaeochromocytomas were diagnosed during pregnancy in 4 patients, all of whom had had previous pregnancies complicated by hypertension and/or fetal abnormalities or deaths. In a fifth patient a tumour was seen in the right adrenal at laparoscopy for sterilization shortly after childbirth.

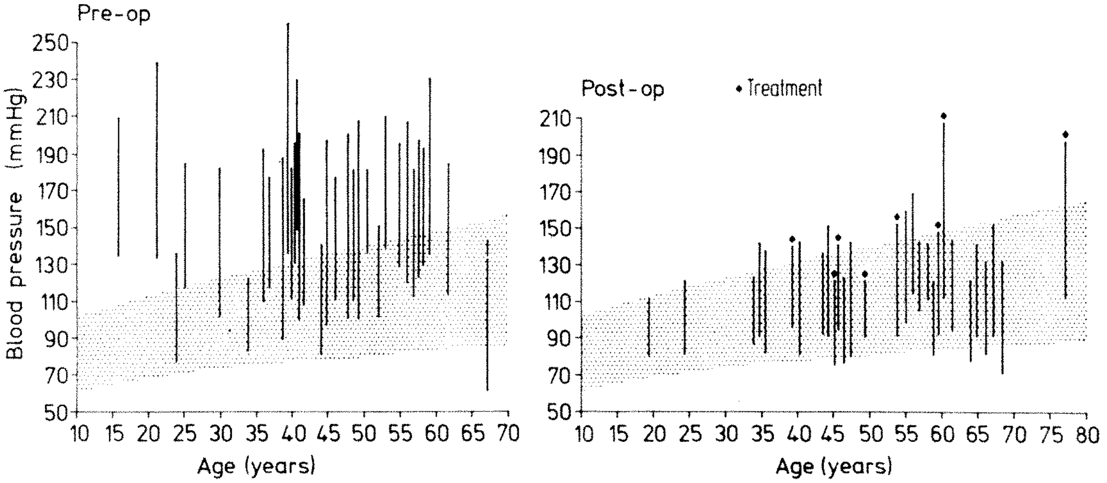

Fig. 1. Blood pressures in male patients before and after operation. The upper and lower borders of the shaded areas depict the mean systolic and diastolic pressures, respectively, of the general population (*see* text). Each vertical line represents one patient and its position indicates his age. Preoperatively, the tops and bottoms of the lines are the means of, respectively, all the systolic and diastolic blood pressure recordings in the 32 patients, excluding those obtained during paroxysms. Postoperatively, they show the *latest* measurements obtained in the 29 patients who survived operation. ◆ indicates that the patient was receiving antihypertensive therapy at the time.

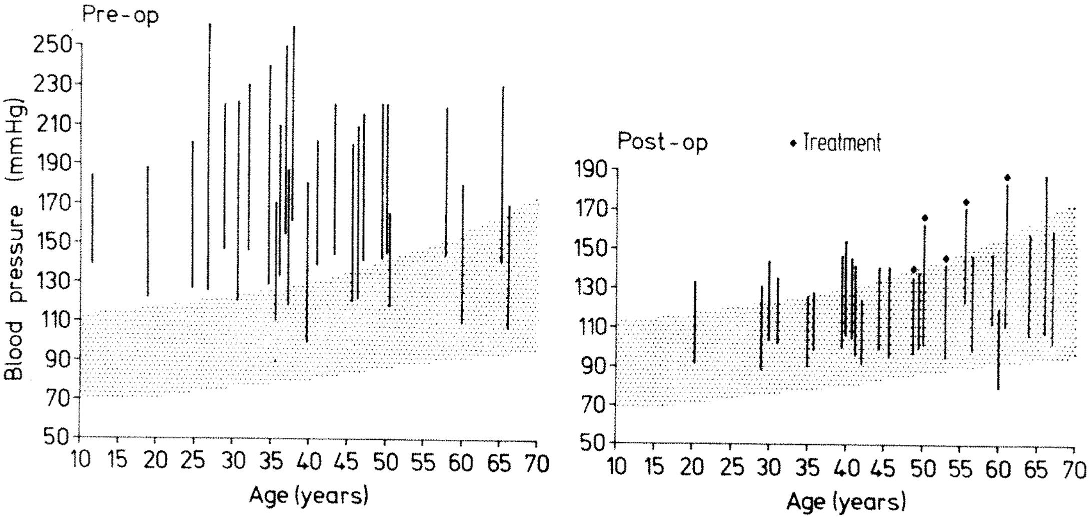

Fig. 2. Blood pressures in female patients before and after operation. The conventions are the same as in *Fig.* 1. Of 26 patients who underwent operation, 25 survived.

Patients diagnosed at autopsy: Phaeochromocytomas had not been suspected during life in 14 patients in whom they were found at autopsy. Retrospective analysis of their case histories suggested that symptoms attributable to their tumours had been present for less than 1 year in 12 (*Table II*). These patients can be divided into three groups according to their modes of death. Those in the first group (9 patients) died from cardiovascular disease, which took the form of myocardial infarct and/or left ventricular failure in 6 (1 of whom died in childbirth), congestive cardiac failure in 1, a cerebrovascular accident in 1 and rupture of an aortic aneurysm in 1. All but the last of these deaths were probably attributable to hypertension and/or catecholamine cardiomyopathy caused by the phaeochromocytoma. The second group (of 3 patients) died from unexpected cardiac arrest associated with relatively minor trauma. One suffered a head injury, 1 underwent vaginal hysterectomy and 1 had an operation for an injury to the eye. All these events presumably precipitated paroxysmal hypertension and acute cardiac dysfunction. Those in the third group (2 patients) died from associated lesions.

One with a cerebellar haemangioblastoma developed neurological signs suggestive of encephalitis, and 1 with a medullary carcinoma of the thyroid, in whom phaeochromocytomas had been sought in life but not found, died from carcinomatosis.

Methods

Diagnosis

The diagnosis of phaeochromocytoma, which was suspected on clinical grounds, involved biochemical tests for the presence of a tumour and, when these were positive, radiological and other investigations to determine its site.

Presence of tumours: The diagnostic biochemical tests included measurement of vanylmandelic acid (VMA), metadrenalines

‡ Postoperatively 8 males and 5 females were receiving antihypertensive therapy when their blood pressures were measured.

(MAs) and catecholamines (CAs) in the urine and often, in the later years, measurement of CAs in the blood. In some patients adrenaline and noradrenaline were measured separately. The tests were usually done several times. VMA was measured in all 58 patients and was elevated in 57 (*Fig.* 3). MAs were measured in 16 and were high in 15 and urinary CA was measured in 37, being high in 34. All patients whose excretion of one was normal had high levels of one or both of the others. Catecholamine levels in the blood have been reported elsewhere (Jones et al., 1977).

Pharmacological tests (particularly with histamine and phentolamine) were used also in many of the earlier patients, but were abandoned because of their unreliability and potential danger.

Localization of tumours: Attempts to locate the tumours were made radiographically, and occasionally by other methods, in 53 of the 58 patients undergoing operation. Four tumours were palpable and, as already mentioned, the side on which the tumour was located was established by the patient's observation of the effect of massage.

The radiologists did not all use the same methods. At first, in Hammersmith and Newcastle, intravenous urography (IVU), presacral insufflation and selective arteriography were used, in that order, until the tumour had been located. Later, selective venous sampling was added to the list of investigations. In Belfast the same course was followed, but insufflation was not used. In the later years all three centres preferred IVU with nephrotomography, followed by arteriography and selective venous sampling, and insufflation was used rarely. Several years ago the form of preparation and control of blood pressure employed for surgical operations was introduced for invasive radiological procedures (*see below*).

Tumours were located accurately in 47 patients (81 per cent) (*Fig.* 3). Two bladder tumours were suspected on arteriography and cystoscopy. One was clearly visible through the cystoscope and the other was seen as an abnormality, though not clearly neoplastic, in the roof of the bladder. Localization was unsuccessful preoperatively in 4 patients, but none of them had caval catheterization. In 5 patients no attempt at localization was made, owing to pregnancy in 3 and because the operations were undertaken as emergencies in 2.

Sites of tumours: Seventy-eight tumours were identified in the 72 patients, and their sites, determined at operation or at autopsy, are shown in *Fig.* 4. All were within the abdomen. In 59 patients (82 per cent) the tumours were in the adrenals, with only a slight preponderance on the right side. In 6 of these the tumours were bilateral. Two of the 6 had Sipple's syndrome (MEA II) and another had several tumours in one gland (counted as one in the total). In 13 patients (18 per cent) the tumours were at extra-adrenal sites, 8 close to the kidneys, 2 in the organ of Zuckerkandl, 2 in the bladder and 1 adjacent to the inferior vena cava above the adrenal.

Sizes of tumours: All the tumours were spherical or ovoid in shape and 63 (81 per cent) measured between 2 and 10 cm in their greatest diameters (*Table VII*). The largest tumour measured 20 cm.

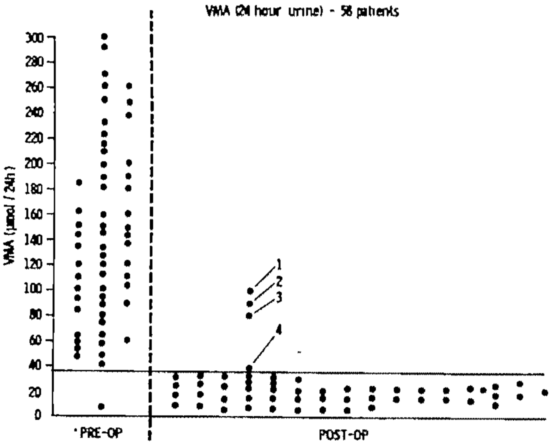

Fig. 3. Urinary vanylmandelic acid excretion before and after operation. Each point represents the means of all readings in one patient. All 58 patients are included before operation. The 54 points after operation represent the latest measurements in those who survived. In all but 3, 2 of whom died and 1 of whom was lost to follow-up within 1 year, the measurements were made from 1 to 20 years after operation. The upper limit of normal is 37 µmol/24 h. Key: 1 and 2 had malignant lesions incompletely removed; 3 had benign locally recurrent disease; 4 possibly had a second tumour.

Treatment

All patients in whom phaeochromocytomas were diagnosed during life were submitted to surgical operation.

Control of blood pressure: Initially the need for pharmacological preparation for operation was not generally appreciated, and it

was not employed. Blood was replaced quantitatively, phentolamine was injected when the blood pressure rose excessively, especially during handling of the tumour, and noradrenaline or metaraminol was infused after removal of the tumour when, as was usually the case, hypotension ensued.

During 1967 a new regimen was introduced, which involved preoperative preparation with an alpha-adrenergic blocking agent, the appropriate use of beta-blockers and infusion to increase the blood volume after removal of the tumour (Ross et al., 1967). After this only 1 patient was treated by the old regimen.

Preoperatively, in Hammersmith and Newcastle, the alpha-blocker phenoxybenzamine was used most commonly and, in Belfast, guanethidine, chlorpromazine or phenoxybenzamine, either alone or in combination, was employed (Bingham et al., 1972). In all centres beta blockade (usually propranolol) was given only in the event of tachycardia or cardiac irregularity (Montgomery and Welbourn, 1975). It was required commonly during operation, but rarely before. Phentolamine and phenoxybenzamine, alone or in combination, were given intravenously in the event of severe hypertension during operation. In addition to the quantitative replacement of blood, additional blood, plasma or dextran was infused rapidly after removal of the tumour and then more slowly until the blood pressure was stable. The volume to be infused was assessed by continuous monitoring, during and after operation, of arterial and central venous pressures. The arterial pressure proved to be the more helpful, since reliance on the latter led to overtransfusion on occasions. The need for beta blockade was assessed by continuous monitoring of the heart rate and the ECG during and after operation.

Formerly the operations were fraught with hazards and with anxiety for the surgeon, anaesthetist and all concerned. After experience of the careful use of effective pharmacological control and blood volume replacement, operations for the removal of phaeochromocytomas became much less hazardous. However, as with any operation, there were sometimes serious complications. One patient, for instance, required an emergency gastrectomy for a bleeding duodenal ulcer 2 days after removal of bilateral tumours. He had papilloedema and retinal haemorrhages before the first operation and lost his sight after the second.

Operations: The abdomen was explored widely and tumours were removed through anterior abdominal incisions, usually midline or transverse epigastric, unless there were special reasons for other approaches (Welbourn, 1977). For instance, lateral thoracoabdominal incisions were used for large tumours, especially on the right, and for patients who had had previous upper abdominal operations on the adrenals or other viscera. Lower incisions were used for tumours sited below the kidneys or in the bladder. Renal biopsies were taken in some patients for evaluation of the effects of hypertension on the kidneys. On five occasions, for various reasons, it was necessary to remove a kidney with a phaeochromocytoma.

Sixty-two operations were undertaken in the 58 patients, second operations being needed in 4. One of these had a previously unsuspected second tumour removed 2 weeks after the first. Two had local recurrences of benign tumours (*see below*). A fourth patient was suspected of having a second tumour, but none could be found on re-exploration.

Operative mortality: The introduction of the new regimen not only transformed the conduct of the operation, but was followed by a reduction in the operative mortality from 18 per cent to 2 per cent (*Table VIII*).

With the old regimen 3 patients died at operation or in the immediate postoperative period. One succumbed from cardiac arrest while being explored in an uncontrolled hypertensive crisis (Cowley et al., 1970), a second suffered a cerebrovascular accident during induction of anaesthesia and the third patient developed cardiac dysrhythmia during operation, remained in cardiac failure and died 3 days later from pulmonary emboli.

Between 1968 and 1976 41 patients were treated surgically with 1 operative death, which was probably due to the overuse of beta blockade.

Pregnancy: All 4 patients whose phaeochromocytomas were diagnosed in pregnancy survived removal of their tumours, but only 2 produced healthy babies. One, in whom the diagnosis was made at 3 months, had her pregnancy terminated by Caesarean section and the tumour removed at the same operation. A second patient, diagnosed at 5 months, was maintained on alpha- and beta-blockers until term, when a healthy baby was born. Treatment was continued and the tumour was removed 2 months later. The third case, diagnosed at 7 months, was treated with phenoxybenzamine, but the fetus died *in utero*. Shortly afterwards, the fetus was removed by Caesarean section and the tumour was excised at the same operation. The fourth patient was not diagnosed until 8 months, but was treated with phenoxybenzamine, underwent premature labour and had a healthy baby. The tumour was removed soon after.

Bilateral tumours: Four patients underwent bilateral adrenalectomy. Three required permanent replacement therapy, but in one sufficient cortical tissue was left for steroids to be withdrawn after a few months. The other 2 patients with bilateral tumours were diagnosed post mortem.

Histopathology and recurrence

Tumours were reported as malignant in 5 patients (*Table IX*), all of whom were diagnosed in life. Three, who had been treated by surgical excision (together with nephrectomy and radiotherapy in 1 case), showed no sign of recurrence after 8, 8 and 9 years, respectively. The fourth, who was first seen with massive local recurrence and invasion of adjacent tissues after operation elsewhere, was treated by partial surgical removal and radiotherapy. One year later he was alive and in fair health, but had clinical and biochemical evidence of recurrence. The fifth had a large tumour adherent to the kidney, necessitating nephrectomy in addition to adrenalectomy. This patient developed widespread metastases, was treated by radiotherapy and cyclophosphamide, but died after 6 months.

Two of the tumours reported as benign recurred locally. One (Sellwood et al., 1970) had had a tumour removed elsewhere 11 years previously (probably with rupture and spillage) and had developed multiple recurrent lesions in the tumour bed, many of which were excised. Ten years later further extensive recurrences had developed retroperitoneally, extending into the head of the pancreas and the lesser sac. They were treated by partial removal and fast neutron therapy, without benefit,

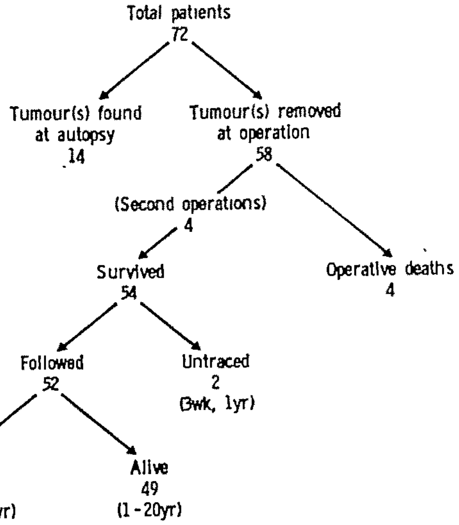

Fig. 5. Overall analysis of outcome in 72 patients.

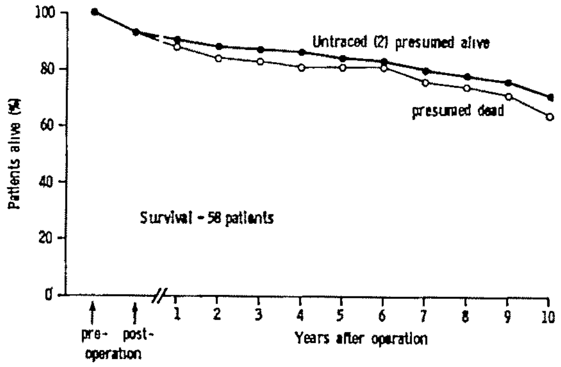

Fig. 6. Survival of 58 treated patients, as percentages, to 10 years after operation. For details *see* text.

but the patient was alive and relatively well 1 year later. The other patient had a benign tumour in the organ of Zuckerandl which was excised incompletely. Multiple local recurrences developed 3 years later and were removed. The patient remained well 6 years later.

Long term results

Survival

Of the 72 patients (*Fig.* 5), phaeochromocytomas were diagnosed at autopsy in 14 and removed by operation in 58. Of the latter, 4 died in the immediate postoperative period and 54 survived (4 of them having undergone second operations without mortality). Two of the 54 were untraced (after 3 weeks and 1 year, respectively) and 52 were followed either to date (1976 or 1977) or until death. Three of these died (after 2 months, 6 months and 9 years, respectively) and 49 were alive at between 1 and 21 years after operation.

The 2 patients who could not be traced in 1976 and 1977 had been well 3 weeks and 1 year after operation and had then emigrated. Two of the 3 late postoperative deaths resulted from the effects of the phaeochromocytoma or of attempts to treat it. One patient, who had had a phaeochromocytoma in the bladder, died after 3 months from pulmonary embolus complicating an operation for intestinal obstruction, caused by a loop of small intestine adhering to the scar on the roof of the bladder. The second, a male of 44, who has been described already, died from widespread metastatic disease 6 months after operation. A third patient, a man aged 48 at the time of operation, died from a myocardial infarct 9 years later.

* Numbers in parentheses, patients untraced.

The survival data (*Table X, Fig.* 6) have been calculated in two ways—on the assumption that both the untraced patients were alive at the time of the final review and on the assumption that both died as soon as they were lost. The two lines on the graph in *Fig.* 6 are very close and show a gradual fall in the number of patients surviving up to 10 years after operation. At this time between 64 and 71 per cent of the series were alive. Thereafter the total number of patients becomes very small, but it is clear that the long term prognosis is excellent.

No separate analyses are shown either for patients with benign or malignant lesions, because their survival was similar, or for those treated by the two regimens, because these affected only the operative mortality.

The 2 patients with multiple endocrine adenopathy diagnosed in life both had medullary carcinomas that could not be eradicated. One, a man of 24, whose thyroid tumour had invaded the recurrent laryngeal nerve and the larynx, was treated by local excision and radiotherapy and he was well 1 year later. The other, a woman of 50, was found to have hepatic medullary metastases when a right-sided phaeochromocytoma was removed. There was no obvious goitre, but the patient developed myxoedema, was treated with thyroxine and remained well 7 years later. She had no evidence of a phaeochromocytoma in the remaining adrenal.

LIBRARY

Blood pressure
Paroxysms of hypertension were relieved by operation in all who had suffered them previously. The mean blood pressures fell appreciably, but sustained hypertension (as defined earlier) persisted in many patients (*Table VI*; *Figs*. 1 and 2). In fact only 6 patients (5 of them male) were normotensive without specific therapy. Eight males and 5 females were receiving antihypertensive therapy, but only 1 (a male) had achieved a normal pressure. The hypertension (at least with specific therapy) caused little disability and no longer threatened life. It was sometimes difficult to discover whether persistent hypertension was due to residual or recurrent tumours or to circulatory or renal damage. Renal biopsy at the time of operation was helpful in a few cases. The neurological state of those who had had strokes before operation remained unchanged.

It has been mentioned that 2 patients had radiological appearances of renal artery stenosis. One, a woman of 39 with paroxysmal hypertension, had a malignant tumour in the left adrenal almost surrounding the renal pedicle. Damage to the renal vein at operation necessitated nephrectomy, but the renal artery showed no histological abnormality. Nine years later the patient had mild sustained hypertension. The other, a woman of 60, with sustained and paroxysmal hypertension, had a left-sided adrenal tumour. No abnormality was found in the renal artery at operation. Three weeks later the blood pressure was 120/80 mmHg, but the patient has not been traced since.

Metabolic disturbances
Of the 9 patients with diabetes, 2 died postoperatively, 4 were cured, 1 still required insulin and 2, 1 of whom had malignant disease, continued to require oral hypoglycaemic drugs.

Hypercalcemia was abolished by removal of phaeochromocytomas in 2 patients, but persisted after the removal of two tumours in a further patient. No cause could be found.

Urinary catecholamines and metabolites
Urinary VMA levels fell to normal after operation in all but 4 patients (*Fig*. 3). Of these, 2 had malignant disease, 1 had locally recurrent benign disease and 1, whose level was only just above normal, is being investigated for recurrence. Urinary MAs were not measured in any patients after operation. Urinary CAs were measured in 21 and were normal in all; they were not measured in the 1 patient whose VMA was slightly raised and who was suspected of having a second tumour.

Discussion

This study reveals that, when the diagnosis of phaeochromocytoma is suspected, localization can be achieved safely and accurately in the great majority of cases and that removal can be accomplished safely, provided that alpha- and beta-blockers are used carefully. Many patients, however, still die before the diagnosis is made.

Autopsy cases
Fourteen, or 19 per cent, of the patients were diagnosed for the first time at autopsy. Others have made similar observations. Graham (1951), in an early collective review, referred to 72 of 207 patients (35 per cent) who died without operation, but it is not clear how many of these had not been diagnosed in life. Scott and his colleagues (1976), with modern diagnostic methods available, found tumours at autopsy in 11 of 44 patients (25 per cent). In the present series different proportions were found at autopsy in the three centres. The highest (35 per cent) was found in Belfast, where two laboratories handle all the pathological material (biopsy and autopsy) from the Province of Northern Ireland, which is a fairly stable community of about 1·5 millions with few patients referred from abroad. The lowest proportion (9 per cent) was in Hammersmith, which accepts many patients, particularly with such rare lesions, already diagnosed or suspected in life, from all over Britain and from abroad. The intermediate position of Newcastle (13 per cent) probably reflects the fact that patients were referred for operation from the whole of northern England, while pathological material was obtained from only two laboratories in Newcastle. The true proportion of patients with phaeochromocytomas which are not diagnosed in life is, therefore, probably at least 35 per cent.

If these patients were diagnosed in life, most of them could be treated effectively. A high index of suspicion and appropriate investigation should bring more cases to light. The pointers are (*a*) hypertension, especially if paroxysmal or in pregnancy; (*b*) paroxysms of any sort, particularly if accompanied by palpitations, sweating, headache, anxiety or pain in the chest or abdomen; (*c*) neurofibromatosis; and (*d*) medullary carcinoma of the thyroid. Appropriate screening tests (urinary VMA, MAs or CAs) applied to these patients should increase the number diagnosed in life.

Chemical diagnosis and localization
There is considerable disagreement in the literature about the best chemical tests for the diagnosis of phaeochromocytoma (ReMine et al., 1974; Harrison et al., 1975). The data show that, in this series, measurement of urinary VMA was more accurate than many other workers have found it. When clinical suspicion continued, despite normal VMA values, other tests were negative in all but one patient (*Fig*. 3). We now regard the measurement of CAs in the urine and/or blood as the most reliable diagnostic method.

False high VMA readings are caused by various factors, including stress and drugs (Montgomery and Welbourn, 1975). With care these factors should be excluded, but we have not always succeeded in doing so.

In this series the location of the tumours was established accurately before operation in 81 per cent of patients and in 89 per cent of those in whom it was attempted. These figures are better than any published previously. Although nephrotomography, selective arteriography and selective venous sampling were the best methods, CAT scanning, ultrasonography and adrenal scintigraphy (Thrall et al., 1978) may play a major role in the future. False positive findings have been reported (Öhman et al., 1974) and, although we did not encounter any in this series, we have done so since.

False positive chemical diagnoses and/or localization studies have caused us to operate, without finding tumours, on 5 patients in the past few years (during the period of this study and since), so that we still have much to learn. However, it is probably better to operate unnecessarily than to fail to operate on a patient who has a phaeochromocytoma.

Location

In this series 13 of 72 patients (8 per cent) had tumours outside the adrenals. This is about the average for all published series, the extremes being zero (Sander et al., 1971—0/20) and 17 per cent (Melicow, 1977—17/100). Tumours outside the abdomen are exceptionally rare. There were none in this series and 2 (2 per cent) in Melicow's.

Bilateral tumours and multiple endocrine adenopathy, type II

In Graham's (1951) review, 19 of 207 cases (9 per cent) had bilateral tumours. The association with medullary carcinoma had not then been described and the number who had both lesions is not known. It is now clear that many of those with bilateral lesions have thyroid tumours also, but the exact number in each series is not always stated. In most recent reports the proportions of patients with bilateral adrenal tumours have been lower than in Graham's series (this series, 6/72—8 per cent; Öhman et al., 1974, 0/20—0 per cent; ReMine et al., 1974, 6/138—4 per cent; Scott et al., 1976, 3/44—7 per cent; Melicow, 1977, 3/100—3 per cent). The only exception is the series of Sander et al. (1971), who found bilateral tumours in 6 of 21 patients (29 per cent), 2 of whom developed second tumours later (38 per cent). Patients with more than two phaeochromocytomas and with multiple tumours in extra-adrenal sites appear to be very rare indeed. However, we have recently treated a patient who had one tumour in the bladder, two others close to it and none in the adrenals.

The proportion of patients with medullary carcinoma (MEA II) (3/72) was similar to that found by Scott et al. (1976) (2/44) and by ReMine et al. (1974) (4/138). However, the numbers of such patients reported in future series are likely to be greater, now that the syndrome is well recognized. It is important to search for phaeochromocytomas in patients with medullary carcinoma, and to treat them first, to avoid sudden death during investigation or treatment of the thyroid lesions (Beaugie et al., 1975). Phaeochromocytomas are so often bilateral (eventually, if not initially) in this syndrome (as in 2 of the 3 patients in this series), that, even if only one is found, bilateral total adrenalectomy is probably the procedure of choice (Carney et al., 1976). It is probably unwise to attempt to leave cortical tissue, in the hope of avoiding the need for replacement therapy. Local recurrence of tumour, sometimes malignant, has been reported in some patients subjected to this procedure (Bloom and Fonkalsrud, 1974; Carney et al., 1976).

Operative mortality

The introduction of the new regimen (preparation with alpha blockade and restoration of blood volume) undoubtedly reduced the hazards of operation, but the apparent reduction of operative mortality (from 18 per cent to 2 per cent) is not statistically significant (*Table VIII*). It is probably real, but information from other reports and from personal inquiries do not allow a valid comparison to be made. For instance, in the series of ReMine et al. (1974) 4 of the 138 patients died (3 per cent), all before the introduction of the new regimen. However, the numbers of patients in each group are not stated and, since 1926, when the first patient was treated, many other significant advances in anaesthesia and general care have been introduced.

Malignancy

It is very difficult, on histological grounds, to determine whether a phaeochromocytoma is benign or malignant, and the same criteria may not have been used in all series. The reported incidence varies from nil (Sanders et al., 1971) to 13 per cent (ReMine et al., 1974) and the pooled data from seven major series, including these two and the present one, is 10 per cent (60/602) (Graham, 1951; Öhman et al., 1974; Scott et al., 1976; Melicow, 1977). It is surprising how well many of those with malignant tumours fare after operation.

Blood pressure

The analysis of blood pressure, and of the effect of operation, in this series is more detailed than in any published previously. The significantly greater degree of hypertension in women than in men before operation is a new observation for which there is no obvious explanation. ReMine et al. (1974) report that 27 per cent of patients (28/103) had persisting hypertension 1 year after operation while the remainder had normal pressures. These authors do not define hypertension. Harrison et al. (1975) state that, even if the pressure remains high for a time after operation, it tends to fall eventually. The present data do not support this view.

Metabolic disturbances

Diabetes is well known in patients with phaeochromocytomas (Manger and Gifford, 1977) and was present in 16 per cent of the patients whom we diagnosed in life. It may be due to catecholamine (particularly adrenaline) excess and be cured by removal of the tumours, as in 4 of our patients. If the diabetes is not relieved by complete removal of the tumours, as in 2 of these cases, it is probably an associated but unrelated, disease. It is worth noting that 2 of the 9 patients (22 per cent) died postoperatively.

The significance of hypercalcaemia in association with phaeochromocytoma is unknown and our observation that removal of the tumour corrected it in 2 of 3 patients agrees with previous reports (Swinton et al., 1972).

Survival

The survival data in this series are more complete than in any previously reported. ReMine et al. (1974) operated on 138 patients, 134 of whom survived. They state that 6 (4 per cent) were lost to follow-up from 1 to 10 years after operation, but conclude that the actuarial survival curve for patients with benign lesions was similar to that for the 'normal' population. They apparently make no allowance for the possible deaths of those who were not traced. In their series patients with malignant tumours fared much worse than those with benign ones. In this series there were only 5 patients with malignant tumours and, of them, only 1 died during the follow-up period. Patients came from so many different countries that the calculation of actuarial survival curves was not appropriate.

Survival data from other reported series are too few for valid comparison.

Pregnancy

In our series 4 tumours were diagnosed during pregnancy. All the mothers survived, but 2 fetuses perished. Of the 2 patients discovered later to have phaeochromocytomas, 1 died during delivery, but both babies survived. This experience is similar to that of others. A review of the literature (Schenker and Chowers, 1971) shows that 58 per cent of mothers and 56 per cent of fetuses die when the condition is not diagnosed.

If the diagnosis is made during pregnancy, the outlook is better for the mother (17 per cent mortality) but the fetal mortality remains high. A phaeochromocytoma should be suspected in any pregnant woman with hypertension or sweating. If a tumour is diagnosed in the first two trimesters, immediate removal under adrenergic blockade is probably advisable, despite the high risk of abortion. Localization by ultrasound (though not by radiography) is safe. The value of long term medical management as an alternative to operation has not been evaluated thoroughly, but there is no evidence that it reduces the fetal mortality.

In the third trimester adrenergic blockade to control the hypertension and to allow the fetus to reach maturity is probably advisable. Delivery by Caesarean section and simultaneous removal of the tumour, if feasible, may then be undertaken at the appropriate time. If the tumour has not been localized, and if it cannot be found easily at operation, alpha blockade may be continued, further localization studies undertaken and the tumour removed later (Montgomery and Harley, 1977).

Recurrence

In one of our patients paroxysms returned some years later and were found to be due to recurrent benign phaeochromocytoma.. This represented benign implantation and growth of phaeochromocytoma tissue spilt during tumour removal and emphasizes the need to ensure total removal of the lesion (Sellwood et al., 1970; Sivula, 1974).

Duodenal ulcer

Three patients (4 per cent) had duodenal ulcers, an incidence no greater than that in the general population. One ulcer, however, was particularly severe, and it seems possible that stimulation of gastrin release by catecholamines may have played a part (Hayes et al., 1972). If so, it is surprising that similar incidents are not encountered more frequently.

Conclusion

The main lessons to be learned from this study are that (*a*) many phaeochromocytomas remain undiagnosed until after death; (*b*) appropriate investigation of suspect patients would probably bring more tumours to light; (*c*) some 90 per cent of tumours are benign; (*d*) appropriate preparation and surgical removal carry a very low operative mortality; (*e*) although hypertension may persist in many, it is susceptible to medical therapy and no longer constitutes a threat to life; and (*f*) the long term prognosis is excellent.

Acknowledgement

We are grateful to many colleagues for referring patients to us, for treating them or collaborating in their management and for help in the preparation of this paper. We thank particularly: Professors C. T. Dollery, R. E. Steiner, J. G. Robson, I. D. P. Wootton, C. V. Harrison, H. K. Weinbren and their staffs, Mr J. I. Burn, Professors G. D. Chisholm and N. J. O'Higgins, Mrs E. Clark and Mr D. Simmonds (Hammersmith); Drs E. M. McIlrath and W. Bingham, Professor E. F. McKeown and Mr D. W. Neill (Belfast); Mrs H. A. Davidson, Miss G. Green, Drs P. M. Hocking, J. A. G. Horton, C. J. Hull and R. Wilkinson, Mr I. F. McNeil and the late Professor A. G. R. Lowdon (Newcastle).

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Already used widely in ● serious infections

INJECTABLE

ZINACEF

cefuroxime sodium

Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics.

Zinacef resists destruction by beta-lactamases
A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.

Zinacef is effective against:
- **most common pathogens**
- **many uncommon pathogens**
- **multi-antibiotic resistant pathogens**

ZINACEF, A BROADER SPECTRUM THAN MOST ANTIBIOTICS

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 grams and infusion pack of 1·5 grams. All containing cefuroxime as cefuroxime sodium.
Indications
Serious bacterial infections, especia where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft-tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Ear, nose and throat infections
Meningitis
Gonorrhoea
Dosage
Adults: Generally 750mg t.d.s. i.m. o i.v. Severe infections 1·5 grams t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary, giving total doses of 3 grams to 6 grams daily.
Infants and Children: 30 to 100mg/kg/ day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in tw or three divided doses.
Gonorrhoea: Single dose of 1·5 grams (2 x 750mg i.m. into different sites).
Contra-indications
Hypersensitivity to cephalosporins.
Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during th early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria. Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage shou be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.
Side effects
Adverse reactions are rare and generally mild and transient, e.g. rashes, gastro-intestinal disturbanc candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).
Storage
Protect from light.
Product Licence number: 4/0263
Price to Hospital (exclusive of VAT)

5 x 250mg	£0·70 per vial
5 x 750mg	£2·10 per vial
1·5 grams	£4·20

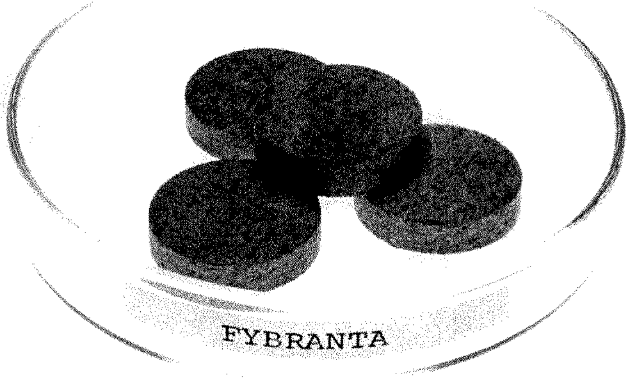
FYBRANTA
cereal fibre



The only fibre
that does all it should

Fybranta contains unprocessed cereal fibre which has been clinically proved more effective than other widely used fibre treatments. Only cereal fibre significantly reduced transit time[1,2] and also lowered intraluminal pressure when tested against other substances.[2] In addition, Fybranta was shown to be effective in increasing stool weight.[1]

Pancreatogram changes in patients with calculous biliary disease

A. T. R. AXON, M. G. ASHTON AND D. J. LINTOTT*

SUMMARY

A successful pancreatogram was obtained at endoscopic retrograde cholangiopancreatography (ERCP) in 53 patients with calculous biliary disease. Twenty-eight patients presented with jaundice and 25 with pain. In both groups there was a high incidence of pancreatogram abnormalities (47 and 48 per cent respectively). These findings demonstrate that the pancreas is often abnormal in the presence of complicated calculous biliary disease even though there may be no recent clinical evidence of pancreatitis and suggest that asymptomatic chronic pancreatitis may be common. The clinical significance of the abnormalities is discussed.

THERE is well-documented evidence that calculous biliary disease is associated with acute pancreatitis (Gillespie, 1973; Kelly, 1974; Waller, 1975; Read et al., 1976; Hermon-Taylor, 1977) but its association with chronic pancreatitis, although reported (James et al., 1974; Read et al., 1976), appears to be less definite and Mallinson (1977) in a recent review article lists calculous biliary disease as a disputed or unconfirmed association of chronic pancreatitis. It is very difficult to estimate how many patients with cholelithiasis develop chronic pancreatitis because, although it is usual to carry out a cholecystogram in patients found to have chronic pancreatitis, it is not normal practice to perform pancreatic tests on patients with uncomplicated gallstones. However, some patients with calculous biliary disease undergo investigation by ERCP which allows assessment of the pancreas. In this paper we have assessed the incidence of abnormal pancreatograms in patients with calculous biliary disease referred for ERCP.

Patients and methods

Patients

During a 2-year period a successful pancreatogram at ERCP was obtained in 53 patients in whom the diagnosis of calculous biliary disease had been established at some stage, i.e. at previous surgery, cholangiography or at ERCP. In many cases (38) biliary calculi were still present.

In 25 patients (group A) upper abdominal pain was the predominant feature and had precipitated referral. The nature of the pain varied from typical biliary colic (11 patients) to pain very suggestive of pancreatitis (7 patients), but in others the pain was atypical upper abdominal discomfort or more severe pain for which extensive previous investigations had failed to reveal a cause (7 patients). Most of the patients in this group could reasonably have had chronic pancreatitis on clinical grounds, especially as 7 had had a previous documented attack of acute pancreatitis. Eighteen patients in this group had had biliary surgery; of these, 10 had had simple cholecystectomy without exploration of the common bile duct. Two had undergone supraduodenal exploration of the common duct and in 1 of these metal dilators had been passed through the sphincter of Oddi. In 4 patients the common duct had been explored transduodenally and sphincteroplasty was performed in 2. Two patients had had their operation more than 15 years previously and operative details were not available. Three operated patients in this group were found to have retained stones.

Twenty-eight patients (group B) presented with jaundice. A number of these also had pain which was, in every case, compatible with biliary colic. There was no clinical suspicion of pancreatitis in any patient of this group and none of them had had a previously documented episode of acute pancreatitis. Three patients had had cholecystectomy and 1 of these had undergone supraduodenal exploration of the common bile duct. In 18 patients a common bile duct stone was found but in 9 calculi were found only in the gallbladder and a transient common bile duct stone was thought to be the most likely explanation of the jaundice, although at the time of examination no stone was seen. One patient with cholelithiasis had stage IV non-Hodgkin's lymphoma which was responsible for the jaundice.

In order to control the pancreatogram reporting, an attempt was made to include a group of patients expected clinically to have normal pancreatograms. It is difficult, in a study of this nature, to identify a 'normal' group because the indications for ERCP are such that patients are referred with either pain or jaundice; as the only symptom of pancreatitis may be abdominal pain, only patients with jaundice can be used as 'normals', but most of these tend to have either calculous biliary disease or pancreatic cancer and so could not be used here. The 'normal' group (group C) therefore comprised 12 jaundiced patients with hepatitis or non-pancreatic neoplasia and in whom, by chance, a technically satisfactory pancreatogram had been obtained during the ERCP undertaken to demonstrate the biliary tree.

Groups D, E, F, G and H are clinical groupings of patients drawn from groups A and B to demonstrate the relationship of clinical factors to pancreatogram abnormality. Group D comprises patients who had not been operated on and who did not have common bile duct calculi at ERCP, it includes patients with gallstones who had had a transient attack of jaundice and who presumably did at one time have a common duct calculus. Group E is made up of patients who are thought never to have had common duct calculi; this group does include patients who had been operated on but none in whom the common bile duct had been explored. These two groups are 'controls' representing the least complicated group of patients in this series.

Group F is made up of the patients found at ERCP to have common duct calculi; Group G consists of those patients previously operated on and Group H those who had received surgical manipulation of the ampullary sphincter. Group J comprises those patients with a previous documented attack of acute pancreatitis.

Methods

ERCP was performed in the conventional way (Cotton, 1977) using a JFB endoscope. All examinations took place in a general radiographic screening room equipped with image intensification. Contrast medium was injected under television control, using sufficient volumes to demonstrate the duct systems without overfilling, and appropriate radiographs were exposed. Urografin 310M (meglumine diatrizoate 65 per cent) (Schering Chemicals Ltd), being suitably concentrated and viscous, was used for the pancreatograms in order to obtain maximum fine branch detail. A dilute contrast medium, Urografin 150 (meglumine/sodium diatrizoate 30 per cent) (Schering Chemicals Ltd), was used for the cholangiograms to avoid 'white-washing' stones.

All 65 pancreatograms were assessed independently by two experienced observers without clinical information. Where there was disagreement the films were reviewed together and a final decision made. Only technically satisfactory pancreatograms were included in this study. A modification of the

---

* Gastroenterology Unit and Department of Diagnostic Radiology, The General Infirmary, Leeds.

classification of Kasugai et al. (1972) was used to grade the pancreatograms as normal, minimal change or gross change (Ashton et al., 1978). Gross change was diagnosed in the presence of (*a*) irregular dilatation of the main duct in the head and body with or without stenoses or obstruction, (*b*) widespread side branch abnormalities such as dilatation, 'nipped' origins and irregular distribution, (*c*) localized lesions such as cysts or calculi. Minimal change was diagnosed when there was (*a*) calibre irregularity of the main duct confined to the tail or (*b*) focal side branch abnormality involving at least three branches. The word 'change' was used rather than 'pancreatitis' because structural rather than pathological features were assessed, although correlation between the two is likely.

Results

The results are shown in *Table I*. Twelve (48 per cent) of the patients presenting with pain (group A) had abnormal pancreatograms; the clinical details of this group are given in *Table II*. When patients presented with clinical pancreatic pain the pancreatogram was usually abnormal whereas those with atypical pain usually had normal appearances. Thirteen (47 per cent) of the patients presenting with jaundice (group B) had abnormal pancreatograms whereas only 1 of 12 (8 per cent) of the normal group (group C) were reported as showing an abnormality. The clinical features of these groups are shown in *Tables III* and *IV*. The one patient in group C with an abnormal pancreatogram had porta hepatis neoplasia.

Table V shows the findings in groups D, E, F, G, H and J. It can be seen that the continued presence of a common bile duct stone, or a previous operation, was not especially likely to be associated with an abnormal pancreatogram. *Table VI* shows the average age of the patients with normal and abnormal pancreatograms and the average age of the 'normal' group.

Examples of abnormal pancreatograms are shown in *Figs*. 1–5. *Fig*. 1 shows gross abnormalities of the main duct and side branches throughout the gland. *Fig*. 2 shows similar gross changes with filling of a cyst in the body. *Fig*. 3 shows a grossly dilated main pancreatic duct containing a stone. The tail of this gland was intentionally not opacified in order to avoid overfilling of the possibly obstructed duct system. *Fig*. 4 shows slight dilatation of the main duct with side branch abnormalities especially in the tail. *Fig*. 5 shows main duct and side branch changes in all regions in a patient with a common bile duct stone.

Table I: PANCREATOGRAMS IN BILIARY DISEASE

Clinical group	No abnormality	Abnormal	% Abnormal
Group A (pain)	13	12	48
Group B (jaundice)	15	13	47
Group C ('normals')	11	1	8

Table II: CLINICAL DETAILS OF 25 PATIENTS PRESENTING WITH PAIN (GROUP A)

Table V: CLINICAL GROUPS

Group	Clinical detail	Normal pancreatogram	Abnormal pancreatogram
D	No operation + no CBD stone at ERCP	7	9
E	No evidence of CBD stone ever	5	10
F	CBD stone present at ERCP	13	11
G	Previous operation	12	9
H	Ampullary dilatation or sphincteroplasty	2	3
J	Previous pancreatitis	2	5

CBD, Common bile duct.

Table VI: AVERAGE AGES OF CLINICAL GROUPS

Group	Average age (yr)
All patients with normal pancreatograms	51
All patients with abnormal pancreatograms	65
'Normal' group	54

Discussion

The interpretation of minor changes of the pancreatogram, observer variation (Reuben et al., 1978) and possible alterations due to ageing (Kizu et al., 1977) may cause problems in assessment. Poor radiographic quality may cause misinterpretation, with possible over-reporting of minor changes. In order to minimize these errors, experienced observers assessed the pancreatograms using criteria which in a previous study had been shown to correlate with Lundh test results (Ashton et al., 1978). In addition a 'normal' group was included in the study and the assessments were made without clinical information. The surprising finding in this series is that pancreatogram abnormalities were present in 47 per cent of all patients in whom there was a history of cholelithiasis. These patients fall into two groups, those who underwent ERCP because of pain and those whose primary symptom was jaundice. Neither of these groups was ideal for a study of this kind. Patients in the first group were sent for ERCP because of difficult pain and in many of them pancreatitis was suspected clinically. The second group was more representative because these were patients who presented with jaundice and in none of them was there any clinical suspicion of pancreatitis before the ERCP was carried out; the 46 per cent incidence of pancreatic abnormality was a surprisingly high finding but it should be emphasized that nearly all the patients in this group probably had common bile duct calculi and so cannot be said to have uncomplicated calculous biliary disease.

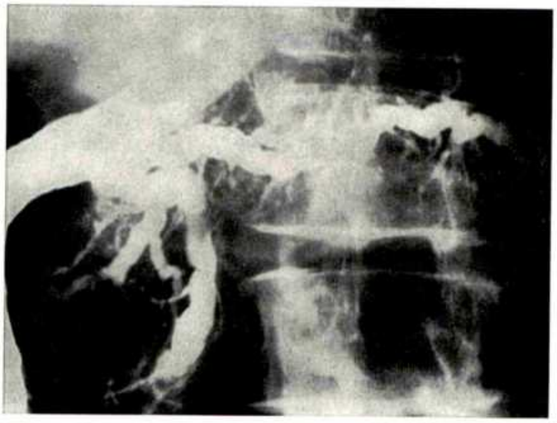

Fig. 1. Pancreatogram of a 62-year-old female referred for endoscopic papillotomy for retained common bile duct stones presenting with jaundice. There is gross abnormality of the whole duct system throughout the gland.

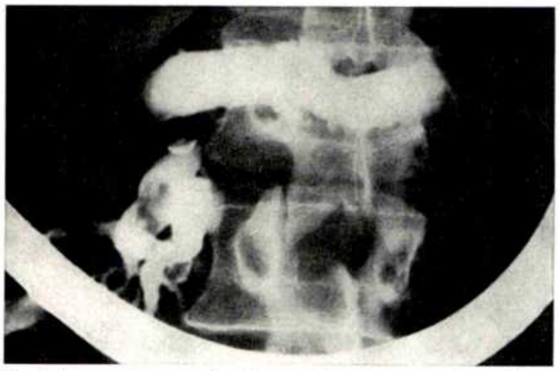

Fig. 3. Pancreatogram of a 42-year-old male presenting with further abdominal pain after cholecystectomy and sphincteroplasty 2 years previously. A stone is present in the main pancreatic duct, which is grossly dilated.

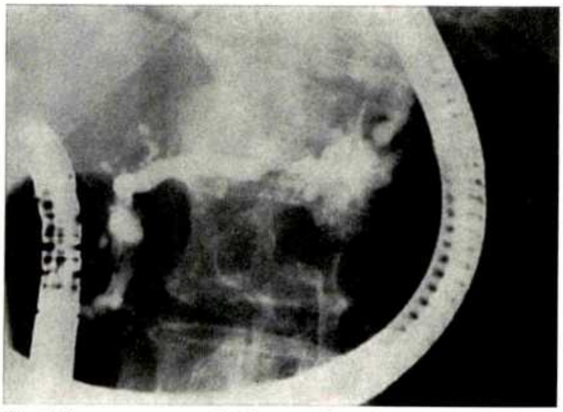

Fig. 2. Pancreatogram of a 70-year-old male presenting with pain and an episode of acute pancreatitis after cholecystectomy. No retained stones were seen. There is a cyst in the body of the gland with gross changes of the main duct and side branches.

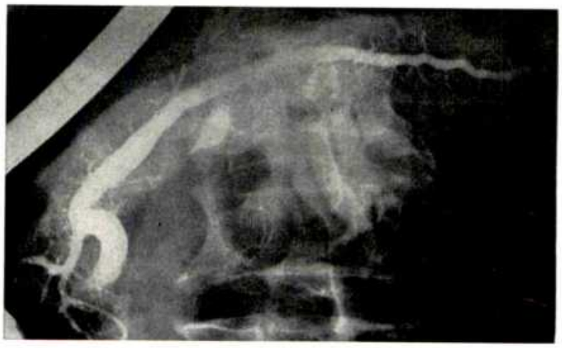

Fig. 4. Pancreatogram of a 70-year-old male presenting with jaundice due to a common bile duct stone. The main pancreatic duct is slightly dilated and the side branches, particularly in the tail of the gland, are abnormal.

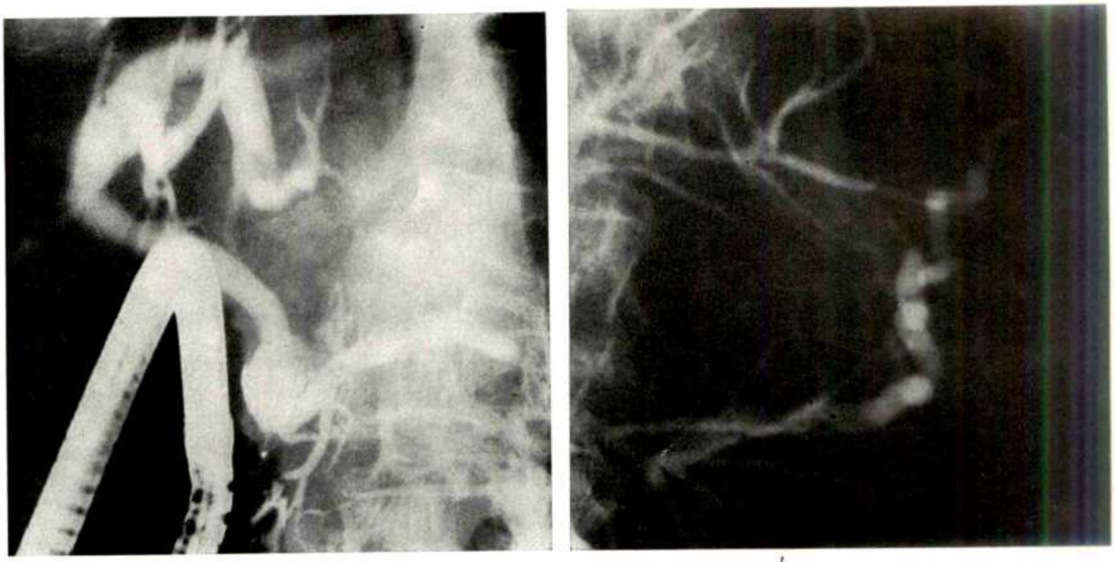
The clinical significance of these changes is speculative. The effect of age upon the pancreatogram is not clearly defined, the results of necropsy studies (Kizu et al., 1977) differing from those of studies *in vivo* (Kasugai et al., 1972; Varley et al., 1976). The patients with abnormal pancreatograms were on average older than both the patients with normal pancreatograms and those in the control group (*Table VI*). However, if pancreatic disease is related to biliary disease then more severe changes are to be expected in those patients who have had biliary disease the longest. Furthermore, in many patients the severity of the pancreatogram changes, some of which have been illustrated, makes it unlikely that age alone is responsible.

The diagnosis of chronic pancreatitis rests upon the demonstration of irreversible structural, functional or microscopic abnormality in the gland. Pancreatography is a relatively crude method of assessing parenchymal damage as interpretation depends upon changes in the first and second order ducts only, and it may be that this had led to an underestimation of the incidence of pancreatic disease. One patient whose pancreatogram was reported normal in this series underwent laparotomy for gallstones a few weeks later and at operation was found to have extensive chronic pancreatitis in addition to gallstones. It is clear from the illustrations that a number of the patients reported here have abnormalities of the pancreatic ducts which represent advanced and widespread chronic pancreatitis which, in some cases, was asymptomatic. Other patients had relatively minor changes whose significance is open to question. These findings may represent a spectrum of disease ranging from the severe to early, possibly non-progressive, or even reversible disease.

If it is accepted that the pancreatogram changes demonstrated here do represent stages in the evolution of chronic pancreatitis it is interesting to speculate whether the presence of a stone in the common bile duct is the factor that triggers the event. Ten patients had undergone surgery for gallstones without exploration of the common bile duct. It seems reasonable to suppose that in these there was no preoperative suspicion of common duct calculi; only 1 of these patients was found to have a common duct calculus at ERCP. A further 6 patients had not been operated on and had never had symptoms or investigations to suggest a common duct calculus. It seems likely then that 15 patients had never had common duct calculi



a *b*

Fig. 5. Pancreatogram of a 74-year-old female presenting with jaundice due to a common bile duct stone. The main pancreatic duct is dilated and there are abnormal side branches throughout.

(group E, *Table V*). Of these, 5 (33 per cent) were found to have an abnormal pancreatogram; this suggests that the presence of a common duct calculus is not necessary for the development of chronic changes in the pancreas, although it is possible that these 5 patients might have had silent common duct calculi which had passed spontaneously.

What is the effect of a previous operation? Twenty-one patients had been operated on for gallstones and of these, 5 had received attention to the ampulla of Vater—either dilatation or sphincteroplasty; *Table V* shows that abnormal pancreatograms were found in 43 per cent of those operated on, and of the 5 whose ampullary sphincter had been interfered with, 2 were normal and 3 abnormal. It is not known whether the pancreatogram changes antedated the operation or whether they had occurred since and the numbers are too small to draw conclusions as to whether ampullary surgery affects the pancreatogram. What does emerge from these figures however is that patients continue to have pancreatogram changes and symptoms of pancreatitis following apparently successful biliary surgery and in the absence of common duct calculi.

These findings raise two important clinical questions. The first of these relates to the differential diagnosis of upper abdominal pain and the difficult problem raised by the new investigation of ERCP which may demonstrate ductal abnormalities in the presence of biliary disease. Should the biliary disease and the pancreatic disease be treated at the same time? It should be emphasized that pancreatograms merely demonstrate an abnormality in the pancreatic duct system, and do not establish the diagnosis of clinical pancreatitis. It is salutary that half the patients with abnormal pancreatograms in this series were asymptomatic as far as the pancreas was concerned; they presented with jaundice. Several of the patients who presented with pain and had abnormal pancreatograms had another lesion as well; 5 of the 12 had biliary calculi at the time of ERCP, a more likely cause of pain. Therefore the presence of an abnormal pancreatogram in the remaining 7 does not necessarily mean that this was the cause of the pain. In view of the generally poor results of conservative pancreatic surgery and the high complication rate of all pancreatic surgery, when biliary and pancreatic disease coexist it is probably wiser to tackle the biliary tract and leave the pancreas alone.

Secondly, should surgery be undertaken on the basis of duct abnormalities shown at pancreatography? Very little data are available to answer this question adequately. There is no consensus as to which operation should be carried out for generalized gross pancreatic disease, and what is needed is a randomized prospective trial comparing surgery carried out on the basis of anatomy with a standard radical operation. It must be emphasized that the indication for operative treatment is clinical and that medical treatments, alcohol withdrawal and, where indicated, biliary surgery should be exhausted before resorting to pancreatic surgery, and only then if symptoms are severe.

Finally, it should be emphasized that this series of patients is a highly selected group; uncomplicated patients with calculous biliary disease are not usually referred to ERCP. The high proportion of patients with abnormal pancreatograms suggests that mild or subclinical pancreatitis is very common in biliary disease but further work is needed to confirm these findings and to discover why, in some patients, probably the vast majority, the pancreas can be disorganized without causing symptoms, while in others with severe incapacitating disease there may be little or no change in the pancreatogram.

Chronic relapsing pancreatitis: a review of 64 cases

J. E. TRAPNELL*

SUMMARY

A collected series of 64 cases of chronic relapsing pancreatitis is reported. Analysis of this material reveals several points of interest. There is a difference in the aetiological spectrum in Britain when compared with reports from France and the United States. In particular, nearly half the British cases were idiopathic. The clinical presentation and the age and sex ratios also varied with aetiology. Endoscopic retrograde cannulation of the pancreatic duct was of little value in confirming a diagnosis of pancreatitis in the problem case. This investigation did, however, demonstrate that a widespread dilatation of the pancreatic duct was a minority finding. In those patients with alcoholic pancreatitis follow-up studies have shown that, if the addiction can be broken, there is a 75 per cent chance that pain will diminish or disappear with the passage of time. The main indication for surgical intervention was severe pain and this study has shown that if strict criteria are observed, a worthwhile relief of symptoms can be achieved. In particular, subtotal pancreatectomy produced good results in up to 85 per cent of cases, although with an appreciable short term postoperative morbidity.

CHRONIC relapsing pancreatitis is still an uncommon condition in the United Kingdom. Experience in the management of the disease must therefore be drawn from collected series of cases and the present report is based on a group of patients referred for surgical treatment over a period of 15 years.

Patients and methods

Between 1961 and 1976, 64 patients with chronic relapsing pancreatitis have been collected. The majority were seen in the past 8 years. There is a minimum follow-up of 1 year with a mean of 5·5 years for all cases. There were 3 deaths in this series attributable to the disease.

The patients were either referred to a surgical outpatients clinic by general practitioners and local consultant colleagues (43 cases) or from other centres for specific consideration of surgical treatment (19 cases). They must therefore be regarded as having been selected because of their possible need for surgery.

Diagnosis

The diagnosis of chronic relapsing pancreatitis was accepted on a combination of clinical, biochemical and radiological findings.

A clinical diagnosis was made on various criteria:

1. A history of a typical attack of acute pancreatitis, with biochemical or operative confirmation, which then drifted on into a chronic relapsing pattern.
2. A patient presenting with typical pain and a history of alcoholism, with or without diabetes, and radiological evidence of pancreatic calcification.
3. Clear evidence of exocrine and endocrine insufficiency, with or without calcification, with or without abdominal pain.
4. Upper abdominal pain 'of pancreatic type' alone.

This last group presented the greatest diagnostic difficulty, for it is now well recognized that it is all too easy to label a patient as suffering from 'pancreatitis' simply because no other cause for his pain can be identified. It is therefore in this group of cases that one looked specifically to the laboratory and the X-ray department for special help.

A raised serum amylase in acute pancreatitis—and a further elevation during a relapse—is clearly of value. Biochemical confirmation of steatorrhea or diabetes is also significant. Apart from this, experience with the present series has shown that the laboratory has little to offer in establishing a diagnosis of chronic relapsing pancreatitis *in the problem case*. Seven patients were referred for intubation and secretin tests. In 4 instances the results were within the normal range. In 2 patients the findings were equivocal and in the remaining case the test was 'unsatisfactory due to difficulty with positioning of the tube'. Of these 7 cases, 6 had the diagnosis confirmed subsequently by other means, while in the remaining patient whose test was normal, it soon became apparent that he had a carcinoma of the body of the pancreas.

Radiological evidence of pancreatic calcification was only detected in 9 of these 64 cases. It was therefore a rare occurrence even in the subgroup with alcoholic pancreatitis. Barium meal examination was performed in 38 patients, usually to exclude peptic ulcer disease. It was useful in the diagnosis of a pancreatic pseudocyst on 5 occasions and confirmed the presence of gastro-oesophageal varices in 1 patient, but in this survey it did not contribute to the primary diagnosis of pancreatitis in any instance.

In the past 3 years, ultrasonography has proved very useful in the detection of the complications of pancreatitis and especially in localization of a pseudocyst. Experience in the use of this diagnostic tool as a means of delineating an enlargement of the pancreas itself is still limited, but in 3 recent cases preoperative assessment by this method correlated remarkably well with the operative findings.

Thirty-one patients underwent endoscopic retrograde cannulation of the pancreatic duct (ERCP). Analysis of the X-rays has revealed two points of interest. First, the ERCP was only of definitive diagnostic value in 6 patients. In the remainder the diagnosis was already clear or the ERCP findings were equivocal. Secondly, only 4 of the 31 cases showed a typical segmental dilatation of the duct of Wirsung—the 'chain of lakes' appearance. A duct of normal calibre was a much commoner finding in this series of cases even when the disease was macroscopically severe.

Eight patients were referred for treatment of 'pancreatitis' with the diagnosis resting to a large extent on minor changes on an ERCP. In 3 instances the pancreas was completely normal at operation. In 5 other patients a quite different cause for the pain was found: in 4 cases there was a peptic ulcer and the fifth patient had a carcinoma of the pancreas. None of these 8 patients is included in the present report but they require mention to emphasize that ERCP alone is of limited value in diagnosis, particularly when the changes are of a minor variety.

It is perhaps a commentary on the difficulty experienced in the diagnosis of chronic relapsing pancreatitis that in this small group the diagnosis was only made at the time of initial assessment in half the patients. In the remainder it emerged over a period of 6 months to 6 years during regular follow-up reviews, either because of some change in one of the biochemical or radiological parameters or because the patient's pain became so bad that surgical intervention was required. In spite of the use of a wide variety of investigations, in 8 patients the diagnosis was only finally established at laparotomy.

Aetiology

The 64 patients divide naturally into two groups (*Table I*). In 33 patients there was a clear history of alcoholism with an intake of spirits in excess of 400 ml per day or the equivalent in wine or beer. No clear aetiological factor could be uncovered in the remaining 31 patients; 4 had undergone cholecystectomy but only one of these patients actually had biliary tract disease—a solitary stone in a functioning gallbladder—and the operation

Table II: EFFECT OF CONTINUING ALCOHOLISM ON PROGNOSIS

	Total	Pain persisting	Pain-free
Drinking	10	8 (4)	2 (1)
Stopped	17	4 (1)	13 (2)

Figures in parenthesis indicate patients who had undergone surgery.

performed in 1964 had not altered the patient's symptoms in any way. All of this group were screened for biliary tract disease, hypercalcaemia and hyperlipidaemia. Also, a most careful inquiry was made via the general practitioner and relatives into each patient's drinking habits so as to exclude alcoholism. It is therefore necessary to place these 31 cases in an 'idiopathic' group.

The presentation and prognosis of these two groups differed and they will be presented separately.

Alcoholic group (33 patients)

Sex and age: Thirty of these patients were men. The average age was 43 years, the oldest patient was 53 and the youngest, who had been drinking half a bottle of gin a day for 5 years, was 18. The majority of cases (25) were in their thirties or forties.

Presentation: Thirty-two of these 33 patients presented with a typical attack of acute pancreatitis and then, as they continued drinking, their clinical symptoms progressed to a chronic relapsing pattern of the disease. In only one instance in this group was the onset insidious.

By the time the diagnosis of pancreatitis was established, 4 patients were found to be diabetic: only 5 showed radiological evidence of pancreatic calcification.

Progress: There were no deaths due to pancreatitis in this group. One patient, however, died during the follow-up period. When first seen in 1961, the patient, aged 42 years, was known to be a severe chronic alcoholic who had been in the habit of taking 18 pints of beer plus one bottle of whisky a day for at least 10 years. He was admitted to hospital for investigation and treatment of a peripheral neuritis but for the preceding 4 years he had suffered recurrent attacks of abdominal pain of varying degrees of severity. Investigations had failed to reveal the cause. While in the ward he developed a further severe attack and a serum amylase of 4250 Somogyi units was noted. Following a stormy illness, the patient recovered and was apparently persuaded to stop drinking. Over the succeeding 2 years, his abdominal symptoms settled and his peripheral neuritis improved, but in 1964 a diagnosis of hepatic cirrhosis was made and this progressed, with the development of ascites, until in 1966 he was readmitted in hepatic pre-coma. He responded to treatment at that time but eventually died of liver failure in 1968. Autopsy confirmed the presence of chronic liver disease; the biliary tract was normal; the pancreas was shrunken and fibrotic.

Five patients in this subgroup of alcoholic pancreatitis were lost to follow-up. In the remaining cases (27 patients) the progress of the disease appeared to depend on whether or not the patient was able to break his addiction (*Table II*). Of the 10 patients who admitted to continued drinking, 8 still had considerable pain in spite of the fact that 4 had undergone some form of surgery. Of the 2 patients who were pain-free—following subtotal pancreatectomy in one—and who were still drinking, it may be significant that their habits had changed. Instead of imbibing half a litre of spirits a day, they were now content with 2 pints of British beer!

By contrast, 17 patients had managed to break their addiction. It is accepted that this is a sensitive area because a patient's story may be most unreliable but each claim was checked with relatives and with the general practitioner. However, the clinical status of these cases differed quite significantly from those who admitted that they were still drinking: 13 patients said they were pain-free, although 2 may have benefited from surgery; 4 patients still had pain, in spite of operation in one case, but 3 of this group were back at work. It is also an interesting feature that in this subgroup those who still had symptoms said that these were lessening with the passage of time, and when seen for follow-up, no patient required regular analgesics.

From an overall view of these cases of alcoholic chronic relapsing pancreatitis, it may be concluded that, if a patient can stop drinking, he has a 75 per cent chance that his symptoms will settle.

Idiopathic group (31 patients)

Sex and age: The sex/age pattern differed in two respects from the previous group. There was a reversal of the sex incidence—only 11 of the 31 cases were men—and the age range was much wider (12–75 years). The average age was 49 with a much more even spread over the years.

Presentation: Only 15 of these 31 patients experienced an initial attack of acute pancreatitis; in the remainder the onset was insidious. Three patients had clear evidence of exocrine and endocrine insufficiency and one of these also showed radiological evidence of calcification. Three other patients also presented with pancreatic calcification.

Progress: There were 3 deaths in this group attributable to pancreatitis. The first fatality occurred in a girl who began to have attacks when she was 13 years old. By the age of 18 she had suffered 11 episodes of pain severe enough to require admission to hospital. A cholecystenterostomy had been performed when she was 14 with no benefit and a distal pancreatectomy with Roux-en-Y drainage (Duval's operation) at the age of 16 years. This gave a remission of her symptoms for 18 months but then the relapses began again. In her final attack she was admitted with severe pain and hypotension. On this occasion she did not respond to resuscitation and died within 48 h in 'irreversible shock'. A careful autopsy revealed only severe chronic pancreatitis affecting the residue of the gland. The Roux loop had healed and separated from the tail of the pancreas. There was minimal fat necrosis but no haemorrhagic or necrotic change in or around the gland.

The second fatality occurred in a lady aged 67. In 1952 a diagnosis of pancreatitis was established at laparotomy when, during a severe illness, a pancreatic abscess was drained and a cholecystostomy performed, even though there was no evidence of any biliary tract disease. The patient then had further recurrent attacks of pain with several admissions to hospital. Between these relapses she suffered increasing chronic upper abdominal symptoms. In 1963 as an elective procedure her abdomen was re-explored. The biliary tract was normal but the gallbladder was removed. The pancreas was noted to be very hard, enlarged and irregular. The body was therefore transected with a view to performing a Peustow procedure but the duct of Wirsung was of normal calibre. The tail of the pancreas and the spleen were therefore removed and the stump of the gland was oversewn. The patient remained well for 72 h but then her condition deteriorated rapidly and she died. At autopsy the cause of death was found to be a *Clostridium welchii* septicaemia, gas being present in the liver. The pancreas was fibrosed but there was no active disease and no evidence of carcinoma. It was noted that the duct of Wirsung and the common duct opened separately into the duodenum.

The third patient who died was a woman aged 52. The initial diagnosis of pancreatitis had been made at laparotomy in 1954. There was no evidence of biliary tract disease at that time. Over the succeeding 8 years the patient was readmitted five times with severe pain but, in addition, she complained of increasing upper abdominal discomfort even between her relapses. First a left perinephric abscess was drained and then, 3 weeks later, at a further exploration a subphrenic abscess was also drained. In spite of this, the patient's condition failed to improve, she deteriorated and eventually died in coma. At post-mortem examination death was found to be due to a staphylococcal meningitis. The pancreas was small and fibrotic with little normal tissue remaining, but in spite of this the patient had never developed diabetes or steatorrhoea during life.

The 28 survivors in this idiopathic group have all been traced and reviewed. Three patients have minimal abdominal symptoms, their main problem being pancreatic insufficiency, which is being managed medically. Of the remaining 25 cases, 11 were found to have mild symptoms of remission and relapse but these were not severe enough to prevent them working normally. There were, however, two features which caused some concern. In nearly all patients there seemed to be a tendency for the pain to be increasing with the passage of time and also serial intravenous cholangiograms have demonstrated a progressive dilatation of the common bile duct in half of this group.

The other 14 patients all had severe pain sufficient to stop them working and to disrupt their lives. It is these patients, as well as some of those with alcoholic pancreatitis, who were considered for surgery.

Surgical treatment

Indications: Surgical intervention was required for two main reasons. In the first place, operation was performed to deal with one of the complications of the pancreatitis such as pseudocyst (5 patients), pancreatic abscess (2 patients) and haematemesis due to splenic vein thrombosis producing gastric varices (1 patient). Secondly, and this was the overwhelming indication, surgery was performed in an attempt to alleviate crippling pain.

Apart from the interventions for pancreatic abscess, operation was always undertaken circumspectly with a considerable period of preoperative assessment. In particular, this has become our policy in patients where an operation is to be undertaken for pain. All patients have been admitted to hospital so as to allow careful observation of the severity of their symptoms and a special record is kept of their analgesic requirements. In some instances, sterile saline injections were substituted for variable periods in order to confirm the genuineness of the patient's symptoms. Home background and the personality of the patients are now studied routinely so as to build up as complete a picture as possible, as dependability of character has proved to be most important in the postoperative management. It is also our practice to stress to the patients the drawbacks of surgery and especially of pancreatic resection if this is under consideration, so as to deter them from operation if possible; this is done in the knowledge that the patient will return and ask for operation if the pain is sufficiently severe. This careful screening has resulted in rejection of several patients who had been specifically referred for operation from other centres, either because it was felt that their symptoms were not in fact arising from the pancreas or because, even though there was some evidence of disease of the gland, the period of observation and our investigations suggested that this was not the main cause of their pain. In the event, only 26 of the 64 patients originally referred for a surgical opinion have so far undergone operation.

Results

Surgery for complications

Five patients required surgery on account of pseudocyst formation. An internal drainage into the stomach was performed and in each instance the short term effect was good. In particular, there was complete relief of pain. However, on longer follow-up, the pain has recurred in 4 out of 5 cases. Two patients have required further surgery at 2 years and 5½ years after drainage, while in the other 2—followed now for 4 and 11 years respectively—the pain is not sufficiently severe to merit a further operation at present. Only 1 of the 5 cases undergoing pseudocyst drainage remains symptom-free at 3 years. An ERCP has been performed on 3 of the 5 patients, one prior to reoperation, and there was no sign of any patency of the internal drainage. In the 2 patients undergoing further surgery, there was no reaccumulation of the cyst nor any direct connection between the stomach and the pancreas.

Two patients required drainage of a pancreatic abscess: one recovered and the other died.

One man who was having small haematemeses regularly every 3–4 months over a period of 4 years underwent a splenectomy 4 years ago and has remained completely symptom-free.

Surgery for control of pain

Three surgical approaches were used in this group of patients. *Biliary drainage procedures*: In the early years of the present series, 7 patients underwent various biliary tract operations, including sphincteroplasty in 3 instances, but in no case was there any lasting benefit. Only one of these patients actually had biliary tract disease—a solitary stone in a functioning gallbladder. Four patients have required further operations in an attempt to control their pain.

Drainage of the pancreatic duct: This was performed in 7 patients. A simple amputation of the tail with anastomosis to a Roux loop (Duval's procedure) was carried out in the girl already mentioned who subsequently died. In the remaining 6 patients either a filleting with invagination (Puestow, 2 cases) or a laying open of the pancreatic duct with a Roux loop onlay *in situ* (4 cases) was performed. All these patients did well initially and obtained relief of their pain in the short term, but on follow-up only 1 of the 6 survivors, a girl of 13 who is now 19, has remained symptom-free, although she has become diabetic. Three patients have required a re-exploration and subtotal resection of the pancreas and it is interesting that on each occasion when the pancreas was exposed, it was found that the Roux loop had healed and separated completely from the gland. The remaining 2 cases have smouldering symptoms; one is an alcoholic who continues to drink.

An ERCP has been performed on the girl who is symptom-free and on 2 patients who still have symptoms but have not required re-exploration. It has not been possible to demonstrate any patency of an anastomosis between the duct of Wirsung and the Roux loop in these 3 patients.

This finding, taken together with the ERCP findings in the pseudocyst patients, leads one to question the long term effectiveness of internal drainage procedures.

Pancreatic resection: An 85–95 per cent resection by the technique recently described (Trapnell, 1978) was performed in 15 cases, all of whom had a small-calibre pancreatic duct. The clinical data for these cases are set out in *Table III*. There was no mortality but high morbidity. Six patients suffered prolonged septic complications and in one of these there was also haemorrhage from the pancreatic bed, requiring multiple transfusions. Four patients in this group were diabetic preoperatively and a further 4 were rendered diabetic by the operation, but it is interesting that in 7 patients who did not become diabetic, 4 had macroscopic disease which was as severe as any in the whole series. Weight change was not a feature in the majority of the cases in this series. Only 2 patients increased their weight significantly postoperatively

FU, Follow-up.
* Patients have stopped drinking.
† These 3 patients were last seen for follow-up in 1975.

(R. B. and N. S.) while one lady (I. A.), who needed to diet, lost 16 kg (*Table III*).

The result of this operation must be judged on its ability to relieve pain. Follow-up studies show that all patients were improved; 9 say they are completely pain-free, 3 have a mild indigestion which they can control by limiting their diet, their life not being affected in any other way. In 3 patients there is an improvement in pain but not sufficient to allow them to return to their work. Two of these cases have a considerable inadequacy of personality which has made management difficult and the control of alcoholism impossible. However, a significant and useful reduction in analgesic requirement has been achieved in each case following operation.

Discussion

In the past 5 years major series of chronic relapsing pancreatitis treated surgically have been reported from Seattle (White and Keith, 1973), Paris (Leger et al., 1974), Michigan (Frey et al., 1967) and Houston (Jordan et al., 1977). When these reports are compared with the present study and also with the review of James et al. (1974), it is apparent that chronic relapsing pancreatitis is still relatively uncommon in the United Kingdom and also that the aetiological pattern is different. In particular, the alcoholic form of the disease is not nearly as common in this country as in North America. In a search for some other cause all patients were screened for hyperparathyroidism and hyperlipidaemia. Biliary tract disease was excluded but other studies (Trapnell, 1966) have shown that gallstone pancreatitis only very rarely progresses to the chronic relapsing form of the disease. It is also notable that with the larger proportion of idiopathic cases available in the present study, an apparently significant variation in presentation between this group and those with alcoholic pancreatitis has emerged. This has not been commented on in previous reports.

The exact incidence of chronic relapsing pancreatitis in Great Britain is not known, for no geographic survey has as yet been published in this country. However, it is interesting that in the course of a 20-year survey in Bristol which yielded 590 cases of acute pancreatitis (Trapnell and Duncan, 1975) a search of hospital records produced just 61 patients coded as suffering from chronic or chronic relapsing disease. Examination of these patients' records showed that only 33 of them met the present diagnostic criteria for chronic relapsing or chronic pancreatitis (Trapnell, 1969). Furthermore, the majority of the 33 patients were pain-free and presented mainly for medical investigation.

The slow and sequential management of the condition is a feature which has emerged during the experience of this series of patients. In a disease characterized by remission and relapse there need be no rush into surgery unless complications develop; when these do occur they can be dealt with on their merits. The present study confirms the view of others (Frey et al., 1976; Jordan et al., 1977) that a conservative policy should be maintained for as long as possible and for several reasons. If surgery is eventually required it may be major and extensive, particularly if a resection is needed. These patients are often in poor general condition due to anorexia and malnutrition. This may result from the severity of their pain alone, but if they are alcoholic as well this often makes them unreliable in their care of themselves. Indeed, 4 patients in this section were verging on becoming vagrants and this accounted for loss in follow-up in this group. Also there may be other diseases secondary to the alcoholism which will complicate the management of the pancreatitis still further, such as peptic ulceration and hepatic cirrhosis.

Then again it has already been stressed that the pain which has been attributed to pancreatitis may not be arising from this cause but from some other condition, or indeed that it may not be organic at all, and both these possibilities add further weight to a policy of conservatism. The longer operation is delayed, the more opportunity there will be to assess these various aspects. Frey et al. (1967) now refer all their patients for psychiatric assessment preoperatively and they have concluded that operation is absolutely contraindicated, however definite the diagnosis and however severe the symptoms, in anyone who is severely depressed or who has suicidal tendencies.

The results of surgical treatment in this series have been variable. The number of cases undergoing drainage of a pseudocyst or pancreaticojejunostomy are too small to allow any real comparison with other reports, but even so the follow-up studies, particularly for pancreaticojejunostomy, are disappointing. This poor showing, especially when compared with the experience of others, would suggest that our criteria of selection for the operation were incorrect. White and Keith (1973), in a large series of patients, found after a mean follow-up of 4½ years that 46 per cent of their patients were symptom-free: 35 per cent had improved. The results from Paris (Leger et al., 1974) were similar, approximately half of the patients followed over a 20-year period being relieved of pain. Jordan has achieved even better results with the same operation (Jordan et al., 1977). He found that 90 per cent of his 25 patients were pain-free. Indeed, as his results are so much better than those of others this would seem to suggest that his criteria of selection were very strict, thus producing his excellent success rate. The finding of a healed Roux loop in the patients who were re-explored is of some interest and the postoperative ERCP assessment of the other patients also suggests that a pancreaticojejunal anastomosis may close off spontaneously. However, this anastomotic closure is not necessarily related to a recurrence of the patient's symptoms. This finding must lead to further speculation as to the role of duct blockage and dilatation as a primary cause of the disease and of the patient's symptoms.

The results for subtotal pancreatectomy obtained for the present series of cases—an 85 per cent relief of pain—are comparable with the findings in the other major reports of this operation (Leger et al., 1974; Frey et al., 1976). It is also interesting that both these other groups, while having no mortality, also experienced a high postoperative morbidity.

Clearly, patients with chronic relapsing pancreatitis are difficult to manage, but some surgical guidelines are beginning to emerge. When operation is required, the procedure should be tailored to the site of the pancreatic disease and, in particular, to the state of the pancreatic duct. Then, on strict criteria, it would appear that operation can benefit those patients with severe pain. This is the only option open in cases of idiopathic pancreatitis where symptoms continue to worsen. For the alcoholic, however, the long term prognosis still depends primarily on whether or not he can break his addiction. If this is possible, then there is a 75 per cent chance that operation will not be required while, if the patient continues to drink, operation may give him some benefit for a while. Eventually his pain is likely to return and, more particularly, he is likely to die of the other complications of chronic alcoholism.

Bile composition and osmolarity in the interpretation of formation of bile stones and their classification

CH. CHAIMOFF AND R. MENACHE*

SUMMARY

We studied the bile and gallstone composition of 38 surgical patients. According to their composition, the stones were classified as: 1, cholesterol stones, when they have more than 60 per cent cholesterol, or 2, pigment or pigment-mixed stones, when they have more than 40 per cent pigments (including stones with more than 30 per cent calcium). In the cholesterol-stone-forming group (24 cases) a 'supersaturation' in the cholesterol component of the bile and a concomitant reduction in bile salts was found. No such bile supersaturation was found in those with pigment or pigment-mixed stones (14 cases), or in the control group (8 cases).

The osmolarity of bile in patients with pigment or pigment-mixed stones is significantly higher than in those with cholesterol stones or in controls.

These results suggest a different mechanism for gallstone formation in the two groups: a 'supersaturation' of cholesterol with respect to bile salts and phospholipids in the formation of cholesterol stones and an 'overconcentration' of all bile components as a whole in the formation of pigment stones.

In an attempt to clarify the aetiology of gallstone formation, we measured in the bile of patients operated on for cholelithiasis the following parameters: cholesterol, bile salts, phospholipids and, for the first time, osmolarity. Chemical analysis of the gallstones was conducted to ascertain the content of cholesterol, pigments and calcium salts. We report the results of our study and the conclusions we have drawn.

Patients and methods

Thirty-eight patients undergoing surgery for gallstones were examined. Eight patients who underwent gastrectomy and had normal liver laboratory tests and normal gallbladders served as controls. The stones and bile obtained during the operation were sent to the laboratory during or immediately after the operation. The gallstones were washed with saline and water, then air-dried at 37 °C overnight and ground in a mortar. The chemical analysis was then conducted according to the technique of Levy et al. (1976).

The fresh bile sample was analysed by the following micromethod: 2 ml of bile fluid were extracted directly with chloroform and, after centrifugation, a portion of this extract (0·2 ml) was used for the estimation of cholesterol by the Liebermann–Burchard reaction, as modified by Burke et al. (1974).

Since 90–95 per cent of bile salts are insoluble in chloroform, a portion of the remaining extracted bile (0·2 ml) was employed for the determination of total cholates, according to the procedure of Sutor et al. (1976). The total bile salts were obtained by assuming that the ratio of total cholate to bile salt remains relatively constant at 1 : 2·5 (Sjövall, 1960), and by taking into consideration the observations of Sutor et al. (1976) as to the variations in and the interpretation of such results.

The concentration of phospholipids was estimated in 0·1 ml of the non-extracted bile through digestion with sulphuric acid, oxidation with 30 per cent hydrogen peroxide and estimation of the phospholipid phosphorus using the method of Goodwin (1970).

By using standards expressed as mmol/l the absolute value of each component was obtained. These results were subsequently converted to percentage components and recorded on triangular coordinate graphs, according to the method of Admirand and Small (1968), for the determination of the solubility status of the main component—cholesterol. The osmolarity of the fresh bile samples was estimated with a Fiske osmometer, model G–66 (Fiske, Massachusetts, USA), operating by the principle of cryoscopy. The results were expressed as mmol/l of total components.

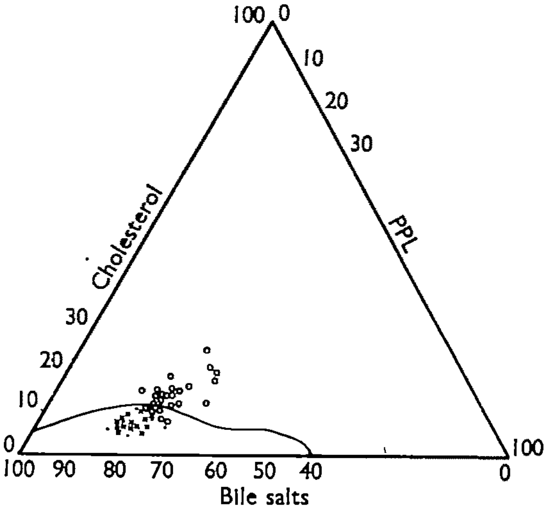

Fig. 1. Percentage composition of bile from 46 patients. ○, Patients with cholesterol stones ($n = 24$); ×, patients with pigment and pigment-mixed stones ($n = 14$); ●, control patients ($n = 8$). PPL, Phospholipid.

Results

The criterion for the definition of 'cholesterol stone' was that of Levy et al. (1976), who found a 60–100 per cent cholesterol content in 68 per cent of gallstones in Israel. Our results, for mean cholesterol content in gallstones, were similar to those reported by Sutor and Wooley (1971) in white Americans—76·2 per cent in women and 68·4 per cent in men. The classification of gallbladder stones according to this criterion is given in *Table I.* The respective bile analyses were arranged in the corresponding groups, and *Table II* shows the percentage composition of the three components for the two groups and the controls. *Fig.* 1 shows the results as expressed on triangular coordinates (Admirand and Small, 1968). This figure shows a 'supersaturation' of cholesterol in 19 of the 24 cases of bile containing cholesterol stones. The analyses of the bile from the 8 subjects in the control group and the 14 with pigment stones are inside the micellar zone (cholesterol 'undersaturation').

The osmolarity of the bile in the different groups is given in *Table III.* This shows that the osmolarity of

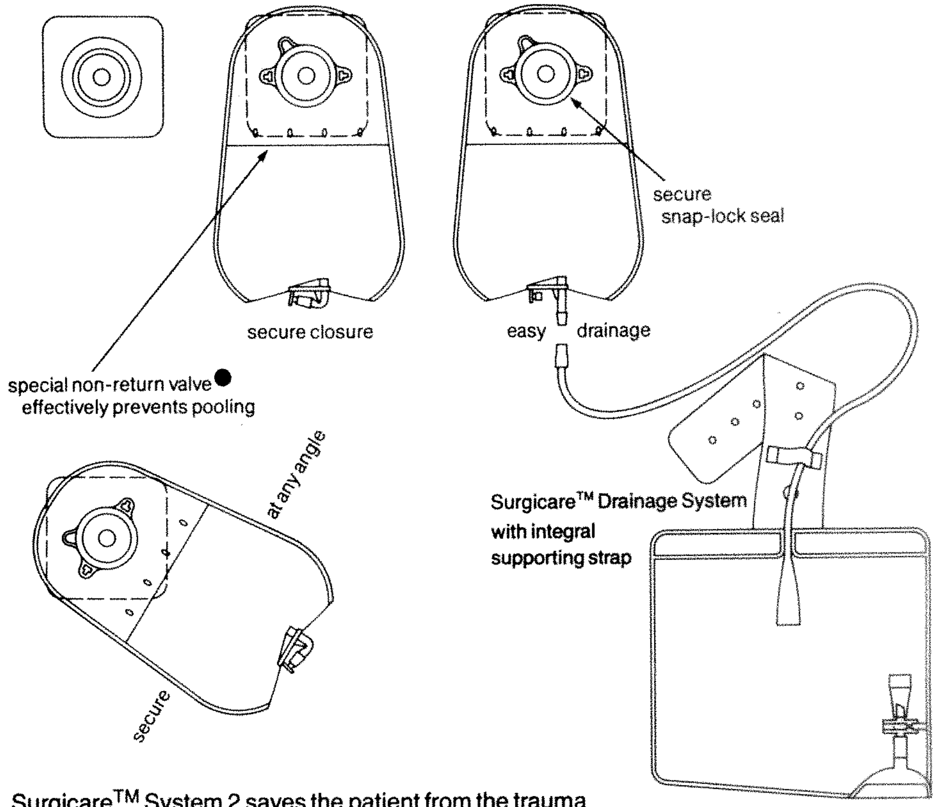
Stomahesive™ Flange
the best in skin care

Urostomy pouches simply snap onto the Stomahesive™ Flange



Surgicare™ System 2 saves the patient from the trauma of peeling off adhesive bags. The Stomahesive™ Flange can be left on the skin undisturbed for several days whilst the pouches are replaced as often as necessary. It makes possible a leak-free attachment of appliances to the skin thereby providing a unique degree of comfort free of irritation and soreness often associated with ordinary adhesives. Surgicare™ System 2 takes full advantage of these benefits which are particularly evident in the management or urostomies.

● The non-return valve permits easy access of urine to the lower part of the pouch and efficiently prevents the return of urine to pool in the area of the stoma thus the Stomahesive™ wafer is protected from the breakdown effects of urine and remains secure and leak-free for several days.

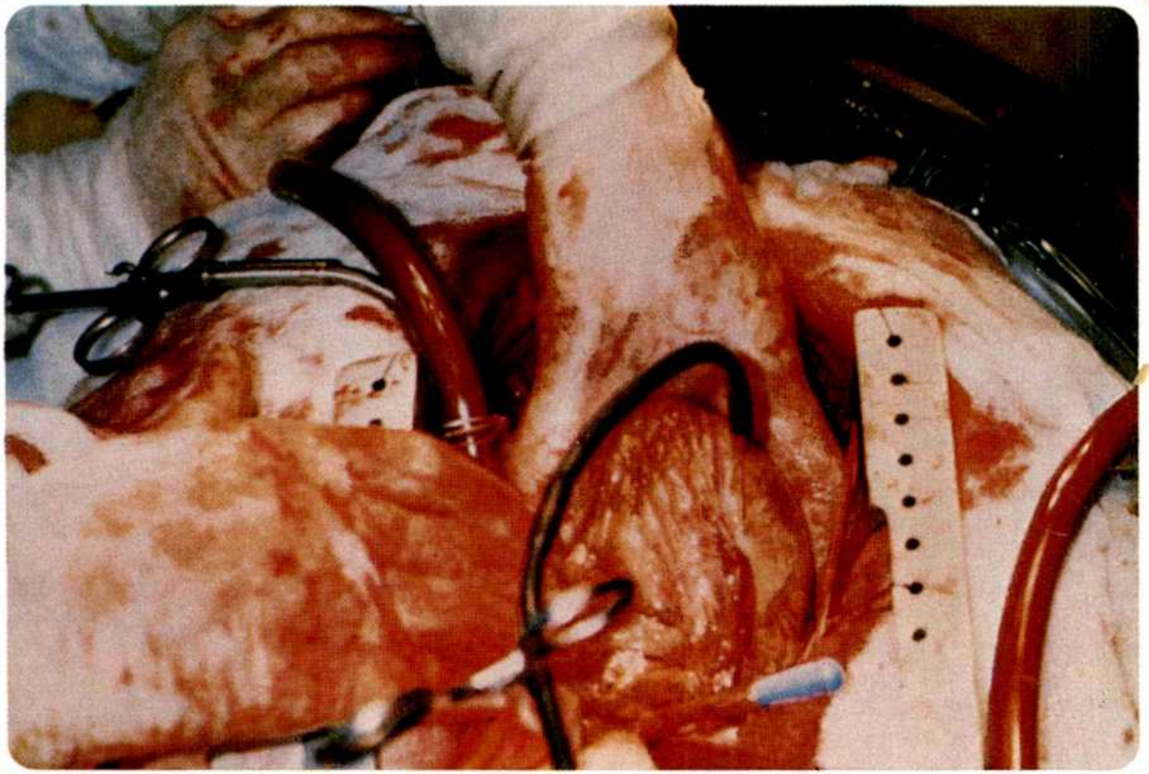
Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted "Magnapen" containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post-operative chest and wound infections. Prophylaxis in major surgery.

Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial qid. Children: 2-10 years: ½ adult dose. Under 2 years: ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL0038/5001, 5009
Contra-indications: Penicillin hypersensitivity, ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product literature before using with intravenous fluids.

Basic N.H.S. Prices: (correct at time of printing: Feb 79).
Capsules: 500mg, £18.06 (100 capsule pack).
Syrup: 250 mg per 5 ml, £3.18 (100ml).
Vials: 500mg, £7.45 (10 vials).

Magnapen is available to hospitals on regional contract dependent upon estimated usage.

Further information on Magnapen is available on request to the company.

Magnapen, BRL and the Company logo are registered trade marks.

* Pure calcium stones included.

Table III: BILE FLUID OSMOLARITY

Group	Bile fluid osmolarity (mosmol/l) Mean±s.d.	Range
Cholesterol stones ($n = 24$)	318±29	274-376
Pigment-mixed stones ($n = 14$)	351±40	286-440
Controls ($n = 8$)	304±20	262-330

bile in those with pigment stones was significantly higher than in either controls or those with cholesterol stones.

Discussion

Our results are in accordance with those found in the literature, which suggest that a 'supersaturation' of cholesterol is associated with the formation of cholesterol gallstones.

The osmolarity of the bile in those with pigment stones was significantly higher than in those with cholesterol stones or no stones. In 3 patients with pigment stones, the osmolarity was outside the scale of the osmometer; the determination was impossible, because the bile was so viscous and rich in mucus. In 2 of these cases the bile contained micro-organisms. These findings suggest that an 'overconcentration' of all bile components (i.e. pigments, calcium salts, proteins, mucus and cellular debris) is associated with the formation of pigment (pure or mixed) stones.

Our findings are in agreement with the views of Trotman et al. (1974), according to whom the formation of pigment stones involves the precipitation of bilirubin, bile salts and as yet unidentified material.

Does obstructive jaundice adversely affect wound healing?*

M. G. GREANEY, R. VAN NOORT, A. SMYTHE AND
T. T. IRVIN†

SUMMARY
The effect of obstructive jaundice on wound healing has been investigated in an experimental study of abdominal wounds in rats following ligation and division of the common bile duct. Animals were jaundiced for 2 weeks before a second operation at which the abdominal wounds were made. The wounds in jaundiced and control animals showed no significant differences in mechanical strength during a 21-day period of study but there was a significant delay in the accumulation of collagen in the wounds of jaundiced animals. The findings suggest that the biochemical changes in the wounds of jaundiced animals did not interfere with wound repair and cast doubt on the thesis that jaundice has an adverse effect on wound healing.

It has been shown that jaundiced patients have an increased incidence of abdominal wound dehiscence and incisional hernia (Ellis and Heddle, 1977). However, a recent clinical study has suggested that impaired wound healing in jaundiced patients is not caused by the jaundice or the associated metabolic disturbance (Irvin et al., 1978). Jaundiced patients may have several other abnormalities which affect wound healing and, in an attempt to determine the effect of jaundice on wound repair, we have studied abdominal wound healing in rats following ligation and division of the common bile duct.

Material and methods

Male Wistar rats weighing 240–280 g were used throughout the study, which was conducted in three parts.

1. Effect of ligation and division of the common bile duct

In this part of the study 55 animals were used. Under open ether anaesthesia, using a clean operating technique, the common bile duct of the rat was exposed through a right subcostal incision and divided between 5/0 silk ligatures, as described by Lee (1972). The subcostal wound was closed with 2/0 Dexon.

Five animals were sacrificed for basal biochemical and haematological investigations of blood taken by cardiac puncture and further groups of 5 animals were sacrificed weekly for 5 weeks. Haemoglobin, prothrombin time, total bilirubin, total protein, albumen, alkaline phosphatase and SGPT were estimated.

2. Estimation of mechanical strength of abdominal wounds

A new techique of testing the mechanical strength of abdominal wounds *in vitro* was used in this study. This technique was based on the measurement of mechanical stress occurring at the time of rupture (σ) of a diaphragm of abdominal musculature distended by water.

In such a system the stress developed is defined by the formula $\sigma = Pr/2t$ (Cottrell, 1964), where P is the pressure applied, r is the radius of the curvature and t is the thickness of the membrane at failure (*Fig.* 1). Therefore, when r and t are calculated for a known value of P, the membrane (rupture) stress, σ, can be determined. Details of the calculation of r and t have been published previously (Van Noort et al., 1978).

One hundred and ninety-two rats were used in this part of the study, divided into two groups of 96 animals each. Animals

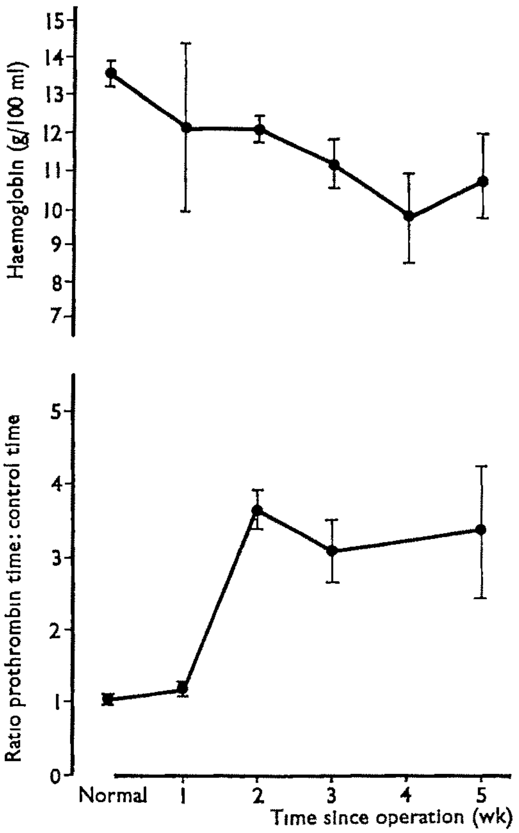

Fig. 5. The haematological changes in jaundiced rats (mean ±s.e. mean).

from one of the groups underwent ligation and division of the common bile duct and the other animals had a sham procedure, without division, and acted as a control group. The rats were anaesthetized again 2 weeks later and a 1-cm incision made in the left side of the abdominal wall. The abdominal muscle was closed as a layer with continuous 3/0 silk and the skin closed as a separate layer.

Jaundiced and control animals were sacrificed in groups of 12 at 1, 3, 5, 7, 9, 11, 14 and 21 days after the operation by overexposure to ether. After sacrifice the skin of the abdominal wall was carefully dissected from the muscular layer and the latter was carefully removed from the animal. Using a specially designed punch, two diaphragms, 30 mm in diameter, were excised from the abdominal muscle. One diaphragm was removed from the unwounded right side of the abdominal wall and the other, with the 1-cm wound at its centre, was removed from the left side. The thickness of the tissue was measured with a dial gauge micrometer.

Both diaphragms were mounted and tested for each animal. The wounds were tested with sutures *in situ* to avoid damage to the tissue. With the sutures *in situ* failure of the wounds occurred between sutures; the sutures therefore do not have a strengthening effect on the abdominal wounds.

The diaphragm tissue was mounted between Perspex rings with an internal diameter of 20 mm using a cyanoacrylic cement. The assembly was then introduced into a Perspex testing chamber and screwed into position (*Fig.* 2). The test chamber was filled with water and pressurized at a constant rate by an infusion pump (Harvard model 900). Distension of the diaphragm of tissue ultimately resulted in the bursting failure of the tissue. The pressure developed in the test chamber was measured with a pressure transducer (AB model 2000 A3) and recorded on an x–y plotter for a permanent record of the pressure-volume curve (*Fig.* 3). The pressure and volume at failure and the original thickness of the tissue were fed into a computer (Data General Nova 320) and the rupture stress for wounded and unwounded tissue (σw and σuw) computed. Measurements of rupture stress of wounded and unwounded tissue from each animal enabled the ratio of the two ($\sigma w/\sigma uw$) to be calculated. The value ($R\sigma$) disposes of variations between individual animals and approaches unity as healing progresses.

3. Estimation of the collagen accumulating in the abdominal wall wounds

One hundred and twelve rats were used in this part of the study. Seventy-two animals underwent ligation and division of the common bile duct and 40 had sham procedures Animals in both groups had 1-cm incisions made in the left side of the abdominal wall at a second operation 2 weeks later. The jaundiced animals were in groups of 9 and the controls in groups of 5. Groups were sacrificed at 1, 3, 5, 7, 9, 11, 14 and 21 days after the second operation.

After sacrifice the muscular abdominal wall was dissected from the animals and, using a special template cutter, a specimen of the wound measuring 1×0·5 cm was excised. This ensured that all samples were of standard size (Irvin, 1974).

Specimens were analysed by estimating the sample collagen values of the tissue using a variation of the method described by Prockop and Udenfriend (1960). Sample collagen was estimated rather than collagen concentration because of possible errors in using the latter value because of oedema and serum proteins in the healing wounds (Woessner, 1968).

Statistical analysis

Wilcoxon's rank sum test was used for the statistical analysis of the effects of ligation and division of the common bile duct (experiment 1). The Student *t* test was used in experiments 2 and 3.

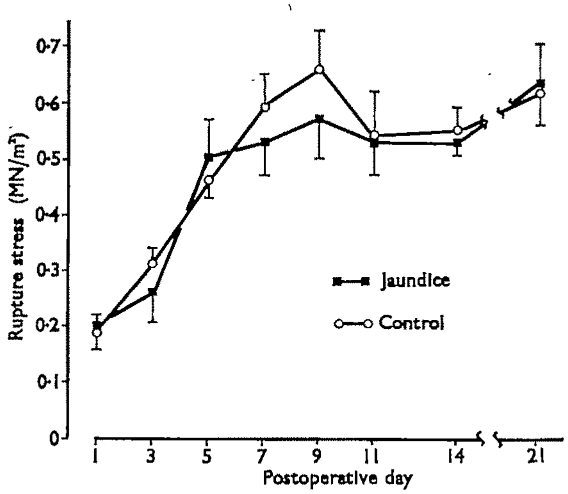

Fig. 6. Rupture stress (MN/m^2) values of abdominal wounds, jaundiced and control animals (mean ±s.e. mean).

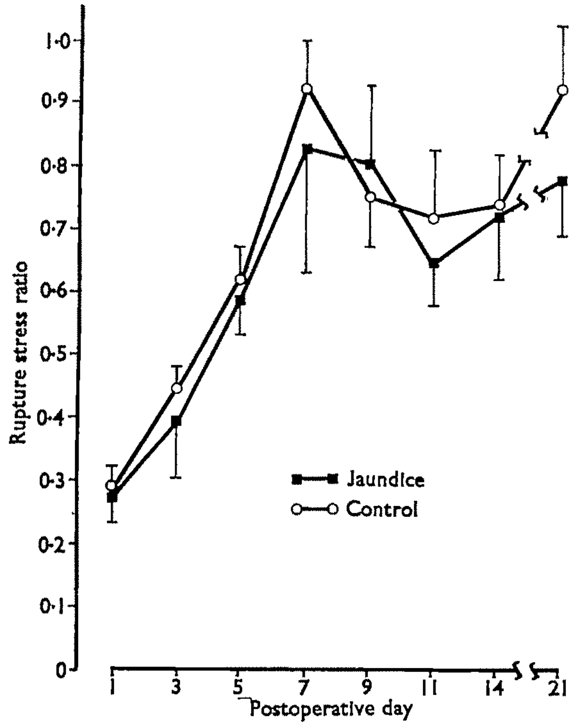

Fig. 7. Rupture stress ratio values of abdominal wounds, jaundiced and control animals (mean ± s.e. mean).

Results

1. *Effect of ligation and division of the common bile duct*

Biochemical estimations: All animals were obviously jaundiced within a few days of the operation and the values of total bilirubin, total protein, albumen, alkaline phosphatase and SGPT are shown in *Fig*. 4. The increase in total bilirubin is significant at 1 week after operation ($P<0{\cdot}001$). In the jaundiced animals there was a significant decrease in serum albumin 2 weeks after operation ($P<0{\cdot}01$).

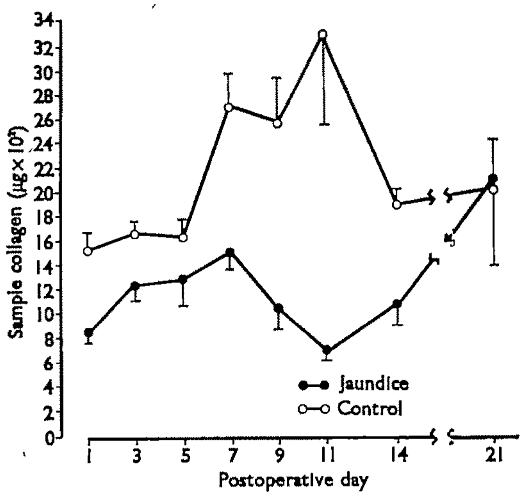

Fig. 8. Sample collagen measurements (mg) of abdominal wounds, jaundiced and control animals (mean ±s.e. mean).

Haematological estimations: *Fig*. 5 shows that there was a fall in the haemoglobin levels in the rats which became significant at 3 weeks after operation ($P<0{\cdot}05$). There was a dramatic rise in the prothrombin time in animals jaundiced for more than 1 week. Unfortunately no prothrombin times were measured in animals jaundiced for 4 weeks because of clotting of samples in the heparinized tubes.

2. *Estimation of mechanical strength of abdominal wounds*

Seventy-three jaundiced animals were available for testing and 86 of the sham control group. Each animal acted as its own control in the measurement of the rupture stress of the abdominal wall. In both groups there was an increase in rupture stress values to the ninth postoperative day and then a plateau (*Fig*. 6). Rupture stress ratio measurements followed a similar trend but peaked earlier, at 7 days (*Fig*. 7). There were no significant differences between measurements of rupture stress of wounded tissue and the rupture stress ratio for the jaundiced or control animals, up to and including the twenty-first postoperative day.

3. *Estimation of the collagen accumulating in the abdominal wall wounds*

Nine of the jaundiced and one of the control animals died in this part of the study, leaving 63 and 39 animals respectively for sacrifice. Sample collagen measurements in the abdominal wounds in jaundiced and control animals are presented in *Fig*. 8. Values in the control animals were significantly higher than in jaundiced rats (with the exception of the fifth postoperative day) until day 21 ($P<0{\cdot}01$). The collagen content of the abdominal wounds in control animals increased gradually until the eleventh day and then fell on the fourteenth and twenty-first days. Abdominal wound collagen in jaundiced animals behaved differently: there was an initial rise until 7 days, a reduction after 11 days and a second rise until 21 days when the values were similar to those of control animals.

Discussion

The evaluation of the effect of jaundice, or any other factor, on wound healing in man is complicated by the presence of other factors in the patient (Ellis, 1977). The jaundiced patient may, for example, have malignant disease or be malnourished. To isolate the factor under investigation it is necessary to undertake animal studies. Bayer and Ellis (1976) have done this in a study of the effects of obstructive jaundice on wound healing in jaundiced rats.

In contrast to the report of these workers, however, in a study in the same animal species and using a similar technique, we have found that ligation and division of the common bile duct not only produced jaundice but also a significant derangement of hepatic metabolism, with anaemia and hypoalbumenaemia. These findings are comparable with those of Than Than (1976) from her animal study.

This experimental study has demonstrated that mechanical strength measurements of abdominal wounds did not show any difference from similar wounds in anicteric control animals. There was some evidence of biochemical disturbance in the healing wounds of the jaundiced animals because collagen accumulated more slowly in the wounds of jaundiced animals.

In their experimental study, Bayer and Ellis (1976) showed that the bursting pressure of abdominal wounds was reduced in jaundiced rats 4 days after operation. However, the wounds in the stomachs of these animals were no weaker than those in controls, although in their histological and angiographic studies the healing process was seen to be delayed in the stomach incisions and in parietal peritoneal defects.

Than Than (1976) showed in radioisotope studies that prolyl hydroxylase activity was reduced in skin wounds of jaundiced rats. This enzyme catalyses one of the rate-limiting stages in the synthesis of collagen. However, in a parallel study she was unable to show any significant difference in tensile strength between skin wounds in jaundiced and comparable control animals.

The studies of Lee (1972) showed that migration of reticuloendothelial cells and fibroblasts into experimental granulomata was delayed in jaundiced animals. Lee concluded from this study that this represented a deficiency in the collagen components of wound healing.

The findings of previous studies show some agreement with the present work in so far as they suggest that collagen metabolism is affected in jaundiced animals. However, there is less agreement with mechanical strength measurements. The discrepancy in mechanical strength measurements may be a reflection of the different techniques of measurement. The lack of standardization and confusing nomenclature have encouraged us to develop a new technique of mechanical testing of wounds in small animals based on the distension of a diaphragm of tissue. We consider that this technique more closely simulates the physiological conditions affecting the healing abdominal wound. Only the muscle layer of the abdominal wall was tested and this is the vital layer in the early stages of healing, the skin is elastic and of little supporting value (Douglas, 1952).

The significance of the changes in collagen metabolism in the jaundiced animals is uncertain. They may be related to other hepatic disturbances, especially hypoproteinaemia, rather than any effect of jaundice alone.

Our recent clinical study (Irvin et al., 1978) also casts doubt on the significance of jaundice in wound healing. The incidence of wound failure, dehiscence and incisional hernia was increased only in those patients whose jaundice was a result of malignant disease. Therefore, it appears that other factors may be responsible for defective wound repair in jaundiced patients.

The surgical treatment of axillary hyperhidrosis

LEIF BERGKVIST AND LENNART ENGEVIK*

SUMMARY

Axillary hyperhidrosis is a common condition and young people often suffer unnecessarily for many years in spite of the availability of good surgical methods for cure. We describe our own modification of Pettersson and Strömbäck's (1970) method of excision of the sweat glands. During the years 1972–6 218 axillary operations have been performed on 109 patients at the surgical clinic in Västerås for axillary hyperhidrosis. We reviewed 104 of these and found that 71 patients were completely satisfied and only 7 unsatisfied. Twelve patients wanted to be reoperated either because they still sweated or because they were unhappy with their scars. Thus, we found that overall the surgical methods are safe, simple and give good results.

AXILLARY hyperhidrosis is a common condition. Patients often suffer for many years without receiving adequate treatment. These patients are continually wet under the arms and the sweat often penetrates the outer clothing. As a result of the sweating, local skin changes occur such as eczema and candidiasis. Bacterial activity causes an odour that is embarrassing for the patient and people nearby. The embarrassment may further increase the sweating tendency. The symptoms associated with hyperhidrosis often first appear at puberty and may result in social isolation.

Anatomy and physiology

The sweat glands in the axilla are of two types, the apocrine and the eccrine glands (Frewin and Downey, 1976). The apocrine glands are found in connection with hair follicles, not only in the axilla but also in the perineum and areolar tissue of the breast. They excrete a milky, odourless fluid, that may be broken down by bacteria into pungent fatty acids. These glands are innervated by the adrenergic fibres of the sympathetic nervous system, and increase their production in response to stress.

The eccrine glands are found throughout the skin and excrete a clear, odourless, salty fluid. They are innervated principally by cholinergic fibres from the thoracolumbar sympathetic nervous system, but have some connection with the adrenergic fibres and are influenced by stress.

It is not clear which type of gland is responsible for the main production of sweat in patients with hyperhidrosis. Rindal and Eskeland (1976) have found an increase of the apocrine glands in patients with hyperhidrosis, while other investigators such as Rigg (1977) doubt whether these glands alone are responsible for the overproduction of sweat. In the majority of cases the aetiology is not known and the histological appearance of the sweat glands is normal (Monro et al., 1974).

Treatment

The medical treatment of hyperhidrosis gives bad results. Anticholinergic drugs have some effect but usually such a high dosage is needed that side-effects become intolerable. The numerous commercial deodorants available have no effect in hyperhidrosis. Shelley and Hurley (1975) describe the use of approximately fifty aluminium salts plus salts of sirconium, zinc, bismuth, copper, magnesium and mercury. They have also listed a number of organic compounds to reduce sweating, including anticholinergic agents, different types of acids, aldehydes and quarternary ammonium compounds. However, Scholes et al. (1978) report good results with 20 per cent aluminium chloride hexahydrate in absolute alcohol. Local radiation has been used but this can give rise to permanent skin damage.

Sympathectomy for hyperhidrosis has been described by Rask and Stefansson (1973), Ellis (1975) and Keaveny et al. (1977). However, as a result of the high complication rate, the operation is rarely used. Different methods that aim to reduce the total mass of glandular tissue have been described. Skoog and Thyresson (1962) described a method of undermining four skinflaps and excising the enlarged sweat glands on the underside. Pettersson and Strömbäck (1970) described a method (*Fig.* 1*a*) with central excision and trimming of the edges. In 1973 Bretteville-Jenssen described an excision method using a Z-flap and Eldh and Fogdestam (1976) described another excision method where the scar was either M- or V-shaped. In 1975 Jemec described a glandular curettage through a small incision. Recently we have adopted a further modification of this method (*Fig.* 1*b*), which has certain benefits when compared with the earlier method of Pettersson and Strömbäck (1970).

Method

The patient lies supine with the arms abducted to approximately 110°. The hairline is marked (*Fig.* 1*b*) and an oval of hair-bearing skin is excised in the inferior part of the hair-carrying area. The superior flap is undermined and the glands excised from its underside. The wound is closed with sutures that include the underlying fascia.

Patients

Between 1972 and 1976 218 axillary operations for axillary hyperhidrosis have been performed on 109 patients. All patients were given a questionnaire and 104 responded (95·4 per cent); 28 were men and 76 women. The average age was 31·5 years and the age range is shown in *Table I*. The average duration of symptoms was 14·2 years, but 5 patients have had symptoms for more than 30 years. The youngest patient in the series, a girl of 15, had had symptoms for only 1½ years (*Table II*). *Table III* lists the presenting problems. All had sweating and the majority also had penetration through their outer clothing. An unpleasant body odour worried 56·6 per cent, whereas 67 per cent found that people around them remarked on their excessive sweating and offered well-meaning advice on treatment. Thirty-one per cent had withdrawn from normal social life because of social and psychiatric problems. Before operation all patients had had some local treatment. All had tried diverse deodorants, 73 had tried some form of 'special' application for hyperhidrosis and 51 had taken some form of medicine, such as anticholinergic drugs or a sedative. No patient had good results from conservative medical treatment. All the patients were operated upon under general anaesthesia

Debrisan beads
magnified ×30
blue transmitted and
red incident light.

Creating the healing environment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing, such as bacteria and wound debris.

Pain, oedema and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast.

Use Debrisan on all moist suppurating wounds such as pressure sores and leg ulcers.

Patients can enjoy the benefits of the healing environment of the future. Today.

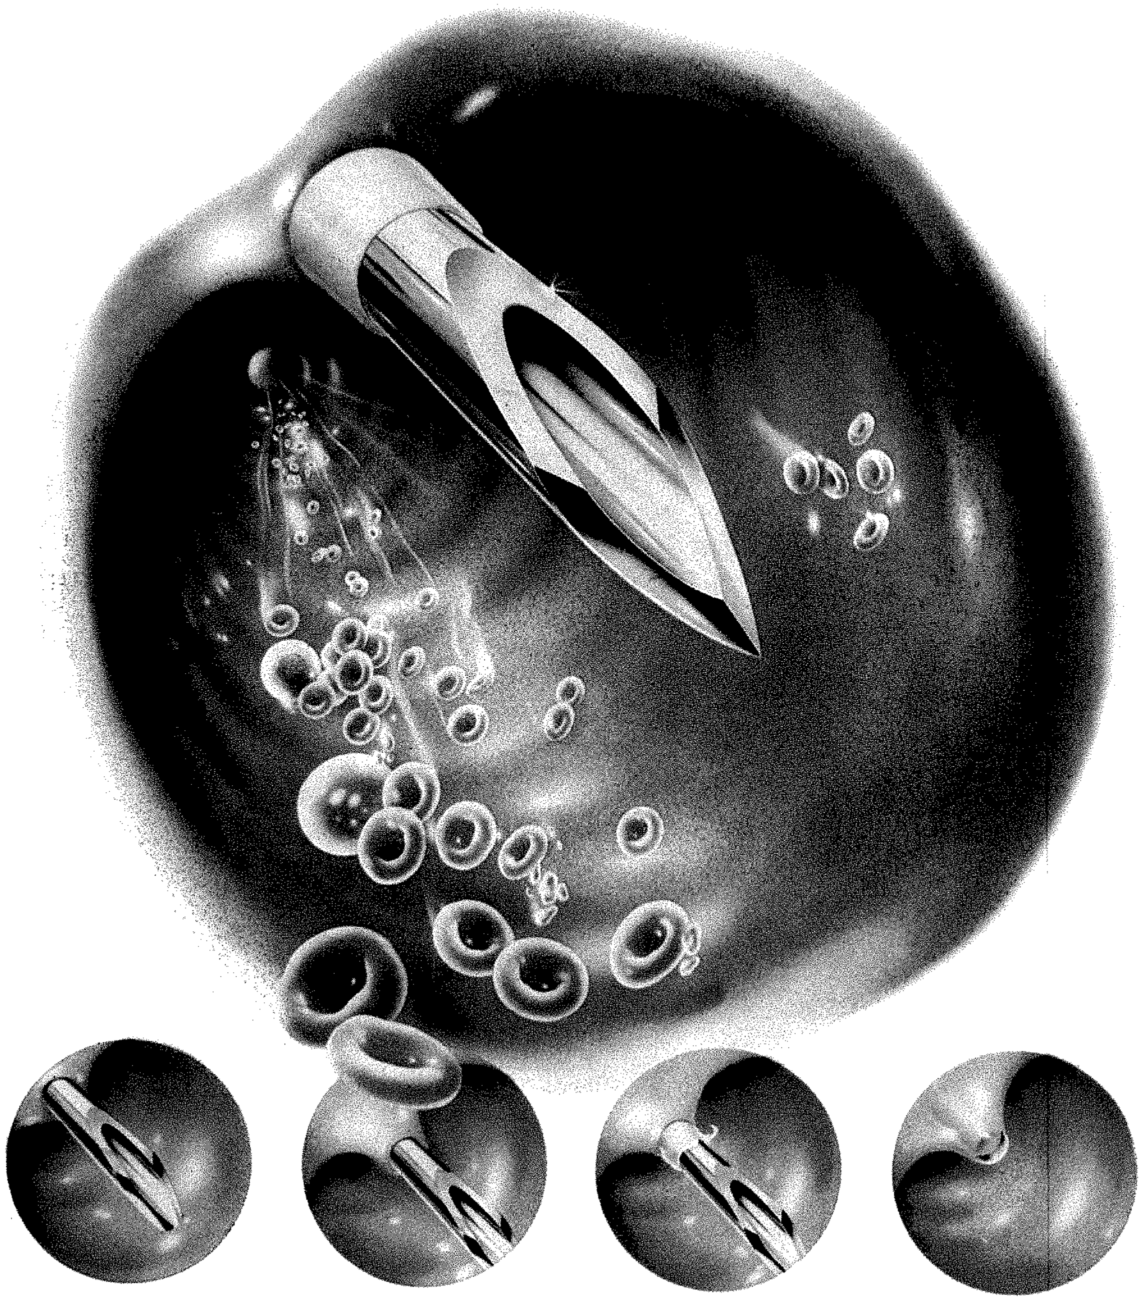
The molecular way to cleanse wounds: promote healing.

The intravenous difference



Where the distance between the cannula tip and the heel of the needle bevel is too great, there is a risk of piercing the opposite vein wall before the cannula is satisfactorily placed within the lumen. With Abbocath®-T, the cannula tip fits snugly behind the heel of the short bevelled needle tip.

An abrupt cannula shoulder requires a high penetration force, leading to tissue and vein trauma, discomfort, and repeat procedures. The electronically formed double taper tip of Abbocath-T requires a minimal penetration force which is constant from cannula to cannula.

A thin cannula shoulder is likely to curl back or shear during insertion, irritating the vein intima and increasing the risk of thrombus formation and phlebitis. The Abbocath-T cannula tip is smooth and sturdy, with no ragged edges or thin spots, and never protrudes over the heel of the needle.

The cannula is left outside the vein lumen following needle withdrawal – resulting in unsightly haematoma and infiltration of i.v. fluid into the tissues. Abbocath-T helps obviate these risks by correct cannula positioning, rapid flashback, and smooth judder-free needle withdrawal.

Surgery Microscope 211

Newly developed stereo microscope with excellent optical performance and extremely compact design. Meets, in particular, the requirements of Oto-Rhino-Laryngology.

These are the features:

- Five step magnification changer from 3x to 30x with constant brightness at all magnifications.
- Bright and evenly illuminated field of view through 6V/20W preadjusted Halogen lamp.
- Small angle of 4° between illumination and observation.
- Interchangeable objectives for working distances of 200, 300 and 400mm.
- Microscope tiltable through three axis, easy to adjust.
- Wide range of accessories such as camera attachment, second observer eyepiece, TV adapter, various binocular tubes and others.

If you require further information or a personal demonstration of the Surgery Microscope 211, please let us know by completing the coupon below.

Intralipid®

soya bean oil emulsion 10% and 20%

the most concentrated source of energy for central and peripheral infusions from the world leaders in complete intravenous nutrition

PRESCRIBING INFORMATION

INTRALIPID 10% INTRALIPID 20%

Presentation A milky-white oil-in-water emulsion

	Intralipid 10%	*Intralipid 20%*
Fractionated soya bean oil	50 g	100 g
Fractionated egg lecithin	6 g	6 g
Glycerol (Ph. Int.)	12.5 g	12.5 g
Water for injections to 500 ml		

pH c. 7. The solution is sterile and pyrogen free.

Uses When feeding patients intravenously the possibility of providing a sufficient amount of energy in the form of carbohydrate is limited by such considerations as hypertonicity, hypervolaemia and the tendency to thrombophlebitis. The development of fat emulsions has overcome these problems. Fat has a high energy value (9.3 calories per gram) and by the use of fat emulsion it is possible to provide a high calorie intake in a relatively small fluid volume. Fat emulsions also have a protein-sparing effect when given in conjunction with amino-acid solutions to correct negative nitrogen balance. The intravenous fat emulsion Intralipid is metabolised in the same way and at the same rate as normal chylomicrons. One litre of Intralipid 10% provides 1 100 calories and 1 litre of Intralipid 20% provides 2 000 calories.

Indications Intralipid fat emulsions are indicated in conditions of severe protein depletion requiring also a high energy intake to compensate for excessive loss of calories following trauma, infection, fever, burns, etc.

Dosage and administration Intralipid 10%: 500–1,500 ml daily in conjunction with intravenous amino-acids. For increased caloric requirements Intralipid 20%: 500–1,500 ml daily in conjunction with amino-acids. Intralipid 10% and 20% are administered by slow intravenous infusion. During the first 10 minutes the drip rate should be adjusted to 20 drops per minute and after half an hour this can be adjusted to a final rate of 60 drops per minute. 500 ml of either emulsion should be given in not less than three to five hours on the first day of infusion. On the first day of infusion it is advisable to administer 10 ml Intralipid 10% or 5 ml Intralipid 20% per kg body weight. Subsequently the dose is usually doubled, and when a larger intake is indicated it may be increased to 3 g fat per kg body weight.

Infant dosage Intralipid 10% or 20%: 15–20 ml per kg body weight in 24 hours.

Contra-indications, warnings, etc. Intralipid is contra-indicated in pathological hyperlipaemia and severe liver damage.

Precautions When daily intravenous fat administration for more than one week is indicated it must be ascertained, in order to prevent the development of cumulative lipaemia, that the patient is capable of eliminating the infused fat from the circulation, and this function can be tested in the following manner. In the morning following the first day's infusion, a citrated blood sample is drawn, preferably when the patient is still in a fasting state. The blood sample is centrifuged at 1 200–1,500 rpm. If the plasma is then strongly opalescent or milky, further infusion should be postponed. In the great majority of cases, plasma is completely clear 12 hours after the conclusion of an infusion of 2 g fat per kg body weight (corresponding to 20 ml of Intralipid 10% or 10 ml of Intralipid 20% per kg body weight). This test should be repeated at weekly intervals.

Pharmaceutical precautions Store at a temperature between 4°C and 8°C, and do not use after the date of expiry indicated. The contents of each bottle are for a single infusion and any residual emulsion should be discarded. No drugs should be added to Intralipid prior to or during infusion.

Legal category No legal restrictions on sale or supply.

Package quantities *Intralipid 10%*: 100 ml and 500 ml. *Intralipid 20%*: 100 ml and 500 ml.

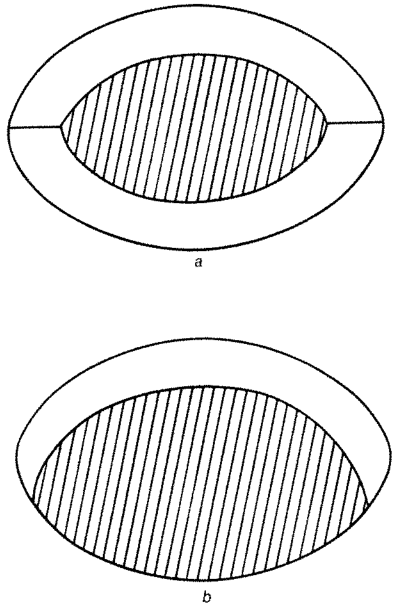

Fig. 1. *a*, The Pettersson–Strömbäck method. The outer line is the limitation of the hair-bearing area. The stretched area is excised and the white field undermined and sweat glands trimmed away. *b*, The authors' method. The inferior oval is excised and the upper flap is undermined. This method thus gives rise to only one skin flap and an interrupted scar line.

as inpatients. Skoog and Thyresson's (1962) four skin flap method was used in 11 patients and Pettersson and Strömbäck's (1970) method (*Fig.* 1*a*) in 93 patients.

Complications

Fifty-six patients have healed without complication, whilst 48 have had some postoperative problems, usually infection. We have classified as infected even those wounds with signs of inflammation around the sutures. It is worth noting that only one patient with infection required antibiotic therapy and that all infected wounds healed in 4–5 weeks. Minor skin necrosis occurred on four occasions and some patients developed cysts and seromas in the axilla that were treated by needle puncture and drainage.

Results

Nearly 70 per cent of the patients were completely satisfied with the operation. Of the other 33 patients (7 men and 26 women), 7 had only one-sided symptoms after the operation. One of these had just as much trouble as before the operation, while the remaining 6 were better but still not completely cured.

Of the 26 patients with bilateral problems, only 6 have as much trouble as before the operation. Seven patients did not experience any improvement after the operation. Thirteen patients (12 women) considered the scar to be cosmetically ugly but only 2 patients had diminished movement in the shoulder. Seven patients would not recommend the operation to a friend, though 2 of these belonged to the group that claimed to be completely satisfied. One of these would not recommend the operation beause of the ugly scar, whilst the other could not give any reason. Four patients found the operation unpleasant. Of the 'completely satisfied' patients, 17 still had some axillary sweating. Altogether 12 patients are to have another operation; some to try to diminish sweat secretion further and some to improve the scar. *Table IV* shows the symptom-free postoperative period for those patients whose sweating recurred. It is interesting to note that even among those patients who were failures there were only 2 who did not experience any diminished sweating; most were improved for a

couple of months. Only 4 patients out of 11 patients operated on according to the four skin flap method were completely satisfied: 2 of these still sweated. Six of the 93 other patients were still bothered by severe arm sweat, one just as much as before the operation. One patient was not satisfied with the cosmetic result.

The average time off work for the whole series was 3 weeks for men and 3·2 weeks for women (*Table V*). Some patients went straight back to work after the operation, while in some cases concurrent illnesses extended the sickness benefit period.

Discussion

Hyperhidrosis is an embarrassing handicap. Medical treatment often fails, although Scholes et al. (1978) report good results with 20 per cent aluminium chloride hexahydrate in absolute alcohol if used continuously. There are several effective surgical techniques. These are of two fundamentally different types: first, the parenchyma reducing operation (Hurley and Shelley, 1963) and secondly, procedures that divide the efferent nerves. Sympathectomy is considered to be a difficult method liable to severe complications such as pneumothorax and Horner's syndrome (Keaveny et al., 1977). The procedures for reducing glandular parenchyma are easy to perform and are associated with no severe complications. In our material we found Pettersson and Strömbäck's (1970) method superior to Skoog and Thyresson's (1962) because the latter was technically more difficult and carried a greater risk of skin necrosis. Our own method has some advantages over that of Pettersson and Strömbäck in giving rise to only one skin flap, so reducing the dissection.

In our series of 104 patients approximately 70 per cent are completely satisfied, 20 per cent, though not quite satisfied, are so much better that they do not wish reoperation and 10 per cent are dissatisfied and need another operation. There were many minor infections but only 7 more severe complications, all of which healed without sequelae. We prefer general anaesthesia as we regard the risk of infection and skin necrosis to be greater with local anaesthesia. All patients were operated on as inpatients; they all preferred to go home the day after the operation although it would be possible for the operation to be performed on a day-care basis. In conclusion, we feel that patients with hyperhidrosis can be helped with an adequate, safe and proved surgical method of treatment. Thirty-three different surgeons all at different stages of their surgical training have operated upon the 104 patients in this series. No significant differences between the results could be found, however senior or junior the surgeon was.

Congenital chylothorax: report of unique case associated with 'H'-type tracheo-oesophageal fistula

J. G. HARVEY, W. HOULSBY, K. SHERMAN AND M. H. GOUGH*

SUMMARY

A case of congenital chylothorax associated with a congenital 'H'-type tracheo-oesophageal fistula is reported. The development of the thoracic duct is described and the possible embryological association with tracheo-oesophageal fistula is discussed. The management of the case is reviewed.

THE first case of neonatal chylothorax was described by Stewart and Linner in 1926, although the condition in adults has been known since 1633 (Bower, 1964). Congenital 'H'-type tracheo-oesophageal fistula, first described by Lamb in 1873 (Ferguson, 1951), is a rare anomaly occurring in 1·8 per cent of all cases of tracheo-oesophageal fistula (Waterston et al., 1962). The association in a single patient is, we believe, unique.

Case report

J. W., a 2·95-kg girl, was delivered by forceps at 38 weeks, subsequent to a pregnancy complicated by hydramnios and pre-eclamptic toxaemia. During the first hour after birth the baby became progressively dyspnoeic and cyanosed with evidence of increasing peripheral circulatory failure. A chest radiograph revealed the presence of a large left pleural effusion (*Fig.* 1). Aspiration of 120 ml of yellow fluid and the insertion of an intercostal drain resulted in rapid improvement. Analysis of the fluid (*Tables I* and *II*) suggested the diagnosis of congenital chylothorax. The diagnosis was confirmed by injecting Patent Blue dye into the web space of the foot and observing the appearance of the dye in the chest drain 3 min after injection.

Lymphangiography was performed through a lymphatic on the dorsum of the foot and revealed normal limb, pelvic and abdominal lymph vessels and glands. A pool of contrast material was visible in the left superior mediastinum 1 h following the commencement of injection (*Fig.* 2). In the first 24 h of life, drainage of fluid by the intercostal catheter amounted to 280 ml. Subsequent drainage continued at a rate of 120–300 ml/24 h for 26 days, amounting to a total of 7·6 litres. Oral feeding was withheld to minimize chyle production and daily fluid requirements were administered intravenously. The volume of chyle lost was initially replaced volume for volume with plasma. On day 10, in the face of continuing chyle loss, parenteral nutrition was instituted and maintained throughout the period of leakage. Spontaneous closure of the fistula was encouraged by the use of a Gregory box to raise the end-expiratory intrapleural pressure to 10 cm of water. Drainage of the fluid was accomplished by means of free drainage through the intercostal drain until day 16 when the drain blocked. Following this, thoracentesis was performed daily until day 26 when a traumatic haemothorax was inadvertently produced, after which the chylous leak spontaneously ceased.

Following the introduction of oral feeding, the baby was noted to have difficulty with feeds, with choking, transient apnoeic attacks and intermittent abdominal distension when coughing. A diagnosis of 'H'-type tracheo-oesophageal fistula was entertained. Cine barium swallow was performed and showed no abnormality. The fistula was successfully demonstrated at bronchoscopy and oesophagoscopy. Operation was performed on day 76 of life. A left supraclavicular approach was used and this demonstrated a fistula at the level of the first

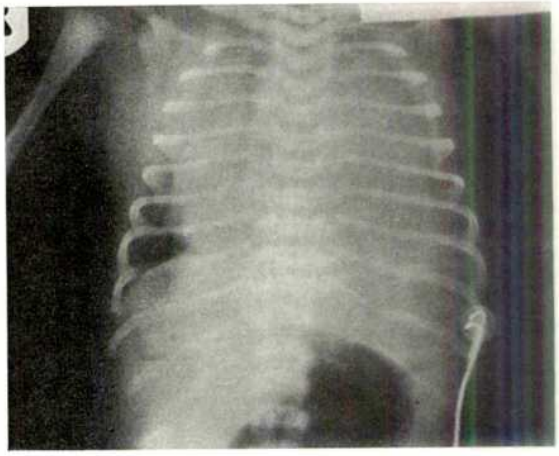

Fig. 1. Chest radiograph 4 h after birth showing left pleural effusion.

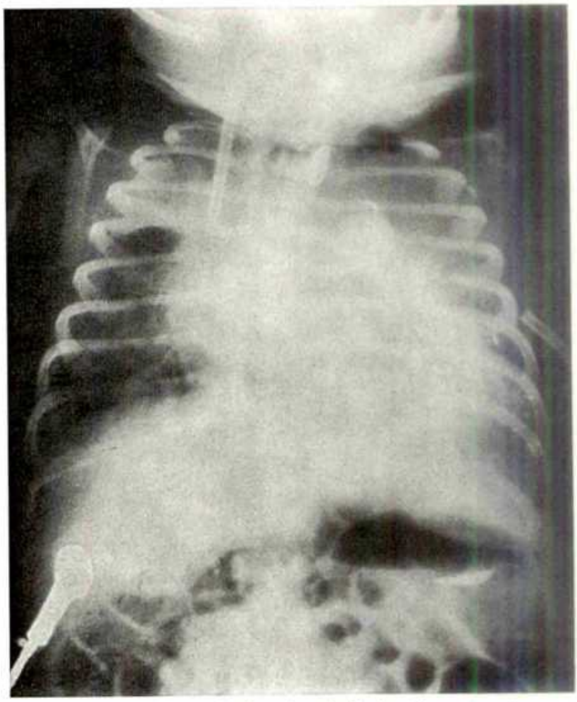

Fig. 2. Chest radiograph showing the leak of lymphangiographic contrast material into the left superior mediastinum and left pleural cavity.

Table I: ANALYSIS OF CHYLE

Chyle	12 Jan. 1977	13 Jan. 1977–2 Feb. 1977	Total
Volume (ml/24 h)	450	250–300	7·6 l
Protein (g/dl)	3·3	—	—
WBC × 10^6/l	1250	—	—
Lymphocytes × 10^6/l	1062	—	—

Table II: ANALYSIS OF PLASMA

Plasma	12 Jan. 1977	21 Jan. 1977	2 Feb. 1977
Haemoglobin (g/dl)	15	11·1	9·2
WBC × 10^9/l	6·1	8·7	12·1
Lymphocytes × 10^9/l	1·09 (18%)	1·66 (20%)	4·2 (35%)
Protein (g/dl)	53·5	59·5	54

thoracic vertebral body. The fistula was ligated and divided. The child made an uncomplicated recovery and when she was seen at 12 months in the outpatient department, she was found to be gaining weight and developing normally. She has had no difficulty with feeding and her chest is now clinically and radiologically normal.

Discussion

Embryological aspects

The formation of the lymphatic system commences at about the 6th week of fetal life as outgrowths of venous endothelium (Sabin, 1902). The thoracic duct is formed by the fusion of caudal outgrowths from the jugular lymph sacs with cranial outgrowths from the cysterna chyli to form a single duct, although the persistence of multiple channels is not uncommon (Van Pernis, 1949).

Lymphaticopleura fistula resulting in chylothorax has been reported in association with a lymphangiomatous malformation of the thoracic duct (Rienhoff et al., 1964). Randolph and Gross (1957) suggested that a congenital abnormality of the duct may predispose to traumatic rupture at the time of delivery.

The separation of the trachea from the foregut should be complete by the 8th week. Any persistent communication presents as a form of laryngeal fissure or as a tracheo-oesophageal fistula usually associated with oesophageal atresia.

Local vascular accidents may arrest the differentiation and development of fetal tissues, and the coexistence of a lymphovascular abnormality and a tracheo-oesophageal fistula at the same somitic level in this infant suggests that some such factor was operative at the 6th to 8th week of fetal life.

Aspects of management

The rarity of congenital chylothorax has resulted in the slow evolution of satisfactory management. Although the 25 per cent mortality (Chernick and Reed, 1970) is probably due to extended conservative management in the absence of adequate nutrition, the incidence of spontaneous resolution in 50 per cent of cases (Randolph and Gross, 1957) and the difficulty of localization of the defect at operation make a trial of conservative therapy worth while. Management should be aimed at the early institution of satisfactory thoracic drainage either by intercostal tube or by repeated thoracentesis. Decancq (1965) suggested that continuous suction should be applied to the intercostal drain in order to promote re-expansion of the lung and to tamponade the visceral pleura against the defect; however, Randolph and Gross (1957) suggested that the use of suction is unwise since the maintenance of a low intrathoracic pressure will tend to keep the duct open and maintain the flow through the fistula.

An attempt was made on our patient to induce spontaneous closure by the use of a Gregory box to raise the end-expiratory intrapleural pressure to 10 cm of water (7·8 mmHg). Experimental work in sheep which demonstrated a mean pressure of 3–5 mm of mercury in the thoracic duct (Hall et al., 1965) would tend to justify this approach. The use of talc to promote pleurodesis at the site of the fistula is recommended by Gingell (1965) and in our case the occurrence of the haemothorax may well have had a similar effect.

The basal flow rate of lymph from the thoracic duct has been shown to be 1·38 ml kg^{-1} h^{-1} and this increases 10 times following a fatty meal (Bessone et al., 1971). Lesser increases in the rate of flow of lymph from the thoracic duct are brought about by protein and carbohydrate. Crandall et al. (1943) showed that in man the ingestion of water by mouth increased thoracic duct lymph flow. In view of these findings, steps should be taken to minimize the flow of chyle by withholding oral feeds or by substituting feeds of medium chain triglycerides which are absorbed directly into the portal system and do not increase the rate of flow of lymph from the thoracic duct (Frazer, 1943; Kosloske et al., 1974).

Total loss of protein in the chylous fistula in our patient amounted to 25 g over 26 days. Replacement of protein loss and the provision of adequate calories were accomplished by means of parenteral nutrition. Recent experience (Kosloske et al., 1974) has shown that this method of alimentation has several advantages over the traditional method of replacement of chyle intravenously (Forbes, 1944). Both lymphocyte depletion and haemorrhagic diatheses secondary to loss of clotting factors in chyle have been described (Brodman et al., 1974). In our case, despite a total loss of $6{\cdot}5 \times 10^6$ lymphocytes, no reduction in the peripheral circulating lymphocyte count was encountered. Coagulation studies showed no defect in clotting ability over the period of leakage. Current management should be directed to conservative therapy which should be maintained in the presence of good nutritional status and adequate ventilatory function for 3–4 weeks, since most fistulas close within this period (Randolph and Gross, 1957). Operative treatment is recommended if leakage continues after this or if there is deterioration of the patient's condition, despite parenteral feeding. Localization of the duct at operation is difficult. Hendy et al. (1962) recommend injection of an intravital dye into the lymphatic system to help localization of the duct. Surgical treatment should consist of suture ligation of the duct above and below the defect and direct suture of the mediastinal pleura.

Tracheo-oesophageal fistula without atresia ('H'-type fistula) in the neonate presents considerable diagnostic difficulty. The fistula is commonly present at the level of the first thoracic vertebra. Our infant demonstrated the triad of feeding difficulty with choking, periodic abdominal distension and recurrent respiratory tract infection, described by Waterston et al. (1962). Barium studies with bronchoscopy and oesophagoscopy should permit the demonstration of the defect in most cases (Sundal et al., 1975), but in some cases exploration on clinical evidence alone may be necessary. Direct ligation of the fistula is all that is required.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Intra-abdominal chylous cyst treated by cyst-duodenostomy

GEORGE W. JOHNSTON*

CHYLOUS cysts are very rare and are usually intrathoracic in position. In 1971 Beasley and Mills reported the successful resection of a chylous cyst from the posterior mediastinum and were able to trace only 9 other cases in the literature, the majority being found incidentally in the thorax at autopsy. This paper reports the successful treatment of an intra-abdominal chylous cyst.

Case report

F. N., a white male, first presented at the age of 35 with a 2-year history of typical symptoms of duodenal ulceration. Barium studies confirmed the diagnosis and medical therapy was instituted. The patient's symptoms became more severe over the next year and surgery was advised. At operation a chronic posterior duodenal ulcer was noted and proximal gastric vagotomy without a drainage procedure was performed. The postoperative course was smooth and the patient remained symptom-free for 1 year. He then presented with acute pain in the right hypochondrium, radiating through to the back. On clinical examination a smooth swelling was noted in the right hypochondrium and a provisional diagnosis of mucocoele of the gallbladder was considered; however, the cholecystogram was normal. Barium studies demonstrated narrowing and anterior displacement of the second and third parts of the duodenum (*Fig.* 1) and endoscopy revealed a hold-up of food in the first part of the duodenum but no mucosal lesion. An insulin test was negative using multiple criteria and serum gastrin and glucagon levels were normal. Liver scan showed some indentation of the inferior aspect of the right lobe. Lymphangiography showed no lymph node abnormality or obstruction to flow but an inferior vena cavogram demonstrated marked compression of the vein from L3 to L1. Since the mass was rapidly increasing in size and becoming much more painful laparotomy was undertaken. At operation the patient was found to have a cystic swelling, about 15 cm in diameter, lying retroperitoneally posterolateral to the second part of the duodenum. The capsule of the cyst was firmly adherent to the duodenum, colon and liver; resection was deemed hazardous. Needle aspiration produced milky fluid which was extractable by organic fat solvents and proved to be chyle. The cyst was treated by internal drainage, the medial wall of the cyst being anastomosed to the lateral wall of the second part of the duodenum, establishing a 1-cm stoma. Biopsy of the cyst wall revealed only dense fibrous tissue with chronic inflammatory cell infiltration. The postoperative course was smooth and there has been no recurrence of symptoms or swelling during follow-up, which extends for more than 3 years.

Discussion

A number of cases of chylous ascites have been reported after truncal vagotomy (Cox et al., 1966; Clain, 1971; Musgrove, 1972). In each instance the accumulation of chylous ascites was noted within 2 weeks of operation and in each case was shown to be due to division of an aberrant lymph channel in the region of the abdominal oesophagus. In this patient the long interval between the vagotomy and the appearance of the cyst makes it more difficult to associate the two events. Possibly damage to a branch of the cisterna chyli in the oesophageal region at the time of vagotomy allowed chyle to track down retroperitoneally behind the lesser sac to the paraduodenal site, and there slowly produce a chylous pseudocyst.

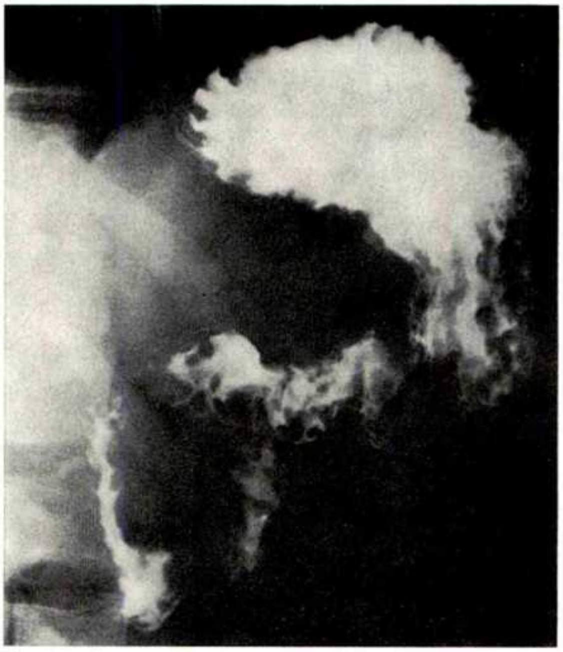

Fig. 1. Barium meal showing compression and anterolateral displacement of the second part of the duodenum.

The chief problem was that of operative management. Excision of the cyst or pseudocyst would have been extremely dangerous because of the absence of planes of dissection and external drainage would probably have produced a troublesome fistula. Because of the high success rate with internal drainage in the case of pancreatic pseudocysts it was decided to use the same principle for this chylous cyst. Cyst–duodenostomy was effective in relieving the patient's signs and symptoms and this success has been maintained in the long term.

Absorption from the jejunum is increased by forward and backward pacing*

JACK COLLIN, KEITH A. KELLY AND SIDNEY F. PHILLIPS†

SUMMARY

In 4 dogs a 75-cm segment of jejunum was isolated from the intestinal stream. Stimulating electrodes were implanted at each end of the segment and recording electrodes at intervals between. The two ends of the segment were fashioned as stomas on the anterior abdominal wall. After recovery, the electrical activity of the segment was continuously recorded, whilst a solution of 100 mmol/l glucose and 90 mmol/l NaCl was infused into the proximal stoma at 2·9 ml/min. Effluent from the distal stoma was collected in 5-min aliquots for three consecutive 30-min periods. In the second period electrical stimuli were given via either the proximal or the distal bipolar electrodes to entrain pacesetter potentials. Both forward and backward electrical pacing decreased the output of water, glucose and sodium from the jejunal segment, but the decrease was significantly greater with backward pacing. We conclude that pacing a segment of jejunum backwards with electrical stimuli produces a greater increase in absorption from the segment than pacing it forwards, a finding which has therapeutic implications in patients with the short bowel syndrome.

PATIENTS who have undergone resection of large portions of small intestine have rapid intestinal transit and suffer from malabsorption, steatorrhea and excessive faecal output of water and electrolytes (Winawer et al., 1966). Treatment of this 'short bowel syndrome' is difficult and often unsuccessful. An effective, safe method of slowing transit through the small bowel and enhancing absorption would be of considerable benefit.

An attractive hypothesis is that intestinal transit can be slowed and intestinal absorption increased by pacing the pacesetter potentials of the small intestine with electrical stimuli.

The pacesetter potentials are omnipresent, regularly recurring, cyclical changes in electrical potential found in the small intestine of both the dog and man (Sarna, 1975). The cycles are generated by a pacemaker located within the first centimetre of the duodenum (Hermon-Taylor and Code, 1971), from where they propagate distally to the remaining small bowel. As they sweep distally, the pacesetter potentials phase the onset of a second type of electrical activity, called action potentials (Sarna, 1975), which in turn triggers intestinal contractions. In this way, the pacesetter potentials set the pattern of intestinal contractions and regulate the transit of content through the small bowel.

Bunker et al. (1967) have shown that the frequency of the pacesetter potentials is identical in the proximal 10–30 per cent of the canine small intestine, while from the mid-jejunum to the terminal ileum the frequency gradually declines. Along the proximal plateau of identical frequency electrical stimuli can entrain pacesetter potentials, increase their frequency and even reverse their direction of propagation (Akwari et al., 1975). Such backward pacing, in turn, reverses the direction of propagation of intestinal contractions along the plateau and slows the transit of content through the paced segment (Kelly and Code, 1977). Pacesetter potentials along the distal frequency gradient can also be entrained if the distal bowel is separated from the duodenal pacemaker by intestinal transection.

We have previously shown (Collin et al., 1977) that backward electrical pacing of an isolated jejunal segment results in prolongation of transit and increased absorption from the segment. The aim of the present study was to determine whether a similar increase in absorption could be produced by forward electrical pacing and to compare changes in absorption with forward and backward pacing.

Methods

Four female mongrel dogs of 13–17 kg were used in the study. In each dog, under pentothal anaesthesia (30 mg/kg) and using aseptic operating technique, a 75-cm segment of jejunum located 50–125 cm from the pylorus was isolated, and the anatomical continuity of the remaining bowel re-established by end-to-end anastomosis. A bipolar stimulating Ag–AgCl electrode was sewn to the serosal surface of the isolated segment 7·5 cm from each end and monopolar recording electrodes were attached at 10-cm intervals between (*Fig. 1*). The electrodes were connected by insulated copper wires to a multipinned socket mounted within a stainless-steel cannula which was fixed to the abdominal wall. The two ends of the segment were fashioned as separate stomas on the anterior abdominal wall. The dogs were allowed a minimum of 7 days to recover from the operation.

In each experiment 50 g of raw liver were fed to the fasted, conscious dog to induce a fed pattern of intestinal electrical activity and to abolish the interdigestive myoelectric complex (Mroz and Kelly, 1977). A 16-French Foley catheter with a 5-ml balloon was passed into the oral end of the segment through its proximal stoma and the balloon inflated in order to prevent loss of fluid from the proximal stoma during the experiment. The segment was next gently irrigated with 100 ml of isotonic sodium chloride to clear the lumen of debris. A solution containing 100 mmol/l glucose and 90 mmol/l sodium chloride (osmolality, 280 mosmol/l, pH 5·3) was then continuously infused through the catheter into the oral end of the segment at 2·9 ml/min. Thirty minutes of infusion were allowed for steady state conditions to be established, after which effluent from the distal stoma was collected in 5-min aliquots for three consecutive 30-min periods. The electrical activity of the jejunal segment was recorded throughout the experiment using a Gould Brush recorder, model 260, with the AC amplifiers set at a time constant of 1 s.

In six experiments in each dog in the second 30-min period electrical stimuli (frequency 0·27 Hz, duration 50 ms, amplitude 4 mA) were given via the proximal bipolar electrode to drive the isolated segment forward. In a further six experiments in each dog electrical stimuli were given via the distal bipolar electrode to drive the segment backward. Stimuli were generated by a model 800 digital pulse generator (WP Instruments). The volume of each 5-min aliquot of effluent was recorded and the glucose, sodium and potassium concentrations measured. The mean volume and output of glucose, sodium and potassium per 5 min were calculated for each 30-min period. Statistical analyses were carried out using the paired *t* test. Differences between the means of the three periods were analysed separately for the two groups of experiments. The mean outputs with forward and with backward pacing were then compared.

In 18 experiments involving forward pacing and in 18 experiments involving backward pacing a bolus of ^{14}C polyethylene glycol (PEG, mol. wt ~4000) was injected in the period before pacing and a further bolus during pacing. The first bolus had passed completely through the loop by the time the second bolus was given. The time taken for 20 per cent excretion of each bolus of ^{14}C PEG was determined and used as a measure of transit.

Results

In all experiments electrical stimulation at the proximal or the distal bipolar electrode during the second 30-min period consistently entrained the pacesetter potentials of the jejunal segment. Before pacing, the rhythm of the pacesetter potentials of the segment was irregular, their frequency variable (range 0·22–0·26 Hz, mean ± s.e. mean 0·24 ± 0·02 Hz) and the direction of their propagation inconsistent (*Fig.* 2). However, during pacing the rhythm of the pacesetter potentials was regular, their frequency was steady and increased to that of the stimulation frequency (0·27 Hz) and their direction of propagation was consistent. When pacing at the proximal site, pacesetter potentials were propagated in a distal direction—from the site of stimulation to the aboral end of the segment. However, when pacing at the distal site, the pacesetter potentials were propagated in the reverse direction—from the site of stimulation to the orad end of the segment.

The volume of output from the distal stoma during the 30 min of forward pacing (mean ± s.e. mean = 6·0 ± 0·5 ml/5 min) was slightly decreased compared to the 30 min before pacing (7·4 ± 0·4 ml/5 min) ($P <$ 0·001). Glucose output during forward pacing (0·48 ± 0·004 mmol/5 min) was also slightly decreased ($P <$ 0·02) compared with the period before pacing (0·56 ± 0·03 mmol/5 min). A similar small decrease in output from the distal stoma during forward pacing was observed for sodium (0·74 ± 0·04 to 0·58 ± 0·04 mmol/5 min, $P <$ 0·01) and for potassium (0·024 ± 0·001 to 0·020 ± 0·001 mmol/5 min, $P <$ 0·02). However, mean transit time during forward pacing (6·5 ± 1·9 min) was not significantly different from before pacing (3·2 ± 0·6 min) ($P <$ 0·1).

During backward electrical pacing fluid, glucose, sodium and potassium output were all markedly decreased compared with both the 30-min periods before and after pacing ($P <$ 0·001). Moreover, the transit time was longer during backward pacing (9·2 ± 2·7 min) than before pacing (2·3 ± 0·3 min) ($P <$ 0·05).

Comparisons were made between the output from the distal stoma during forward pacing and backward pacing of the jejunal segment. During backward electrical pacing output was significantly less than during forward pacing for water ($P <$ 0·001) (*Fig.* 3), glucose ($P <$ 0·001) (*Fig.* 4), sodium ($P <$ 0·01) (*Fig.* 5) and potassium ($P <$ 0·01) (*Fig.* 6).

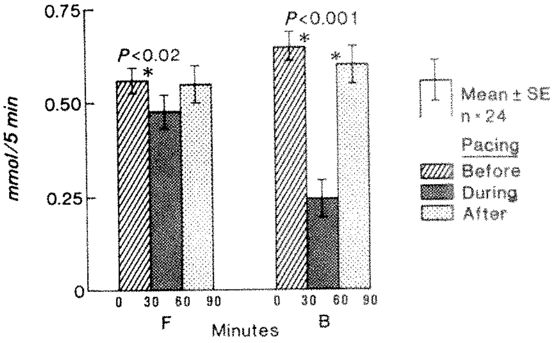

Fig. 4. The effects of forward and backward electrical pacing on the output of glucose from the distal stoma of the jejunal segments. F, forward pacing; B, backward pacing. * Mean differs from that during pacing. Comparison of F and B, $P <$ 0·01.

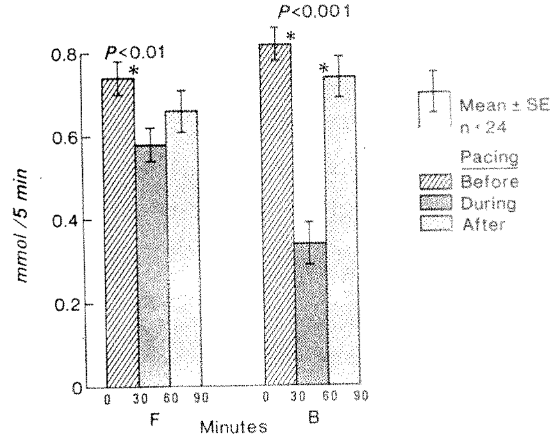

Fig. 5. The effects of forward and backward electrical pacing on the output of sodium from the distal stoma of the jejunal segments. F, forward pacing; B, backward pacing. * Mean differs from that during pacing. Comparison of F and B, $P <$ 0·01.

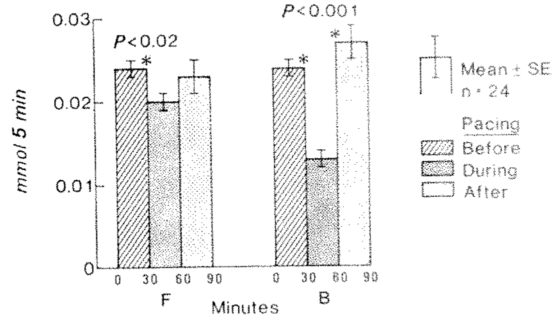

Fig. 6. The effects of forward and backward electrical pacing on the output of potassium from the distal stoma of the jejunal segments. F, forward pacing; B, backward pacing. * Mean differs from that during pacing. Comparison of F and B, $P <$ 0·01.

Discussion

It has previously been shown that application of appropriate electrical stimuli to the small intestine can entrain pacesetter potentials, increase their frequency and result in propagation of pacesetter potentials from the site of stimulation to more distant bowel (Akwari et al., 1975). These experiments demonstrate that in a segment of proximal jejunum entrainment can also be consistently achieved and can be maintained for at least 30 min.

The mechanism as to why such entrainment leads to increased absorption during forward pacing is not clear. Gregory (1950) showed that increasing the contractile frequency along a length of small intestine slowed transit of content through that length. It might be expected, therefore, that an increase in pacesetter potential frequency, and hence of action potential and contraction frequency, would slow transit, which might in turn increase absorption by prolonging contact of the intestinal content with jejunal mucosa. However, transit was not consistently slowed during forward pacing. None the less, the explanation for the enhanced absorption with forward pacing may be related to an increased contractile frequency produced by the pacing. More likely is that increased contractile frequency effectively stirs intestinal content, disrupting the barrier to absorption posed by the unstirred layer of content adjacent to the mucosa. Absorption could thereby be enhanced. Experiments measuring motor activity during forward pacing are required.

The mechanism of the more marked enhancement of absorption with backward pacing as compared to forward pacing seems likely to be related to the orad propagation of the pacesetter potentials produced by backward pacing. Both forward and backward pacing regularized the rhythm and direction of propagation of the pacesetter potentials and increased the frequency of the pacesetter potentials to that of the pacing stimuli, but only backward pacing resulted in propagation of the cycles in an orad direction. Such orad propagation of cycles, hence of contractions, slows or reverses transit of content through the bowel, as reported by us in past papers (Collin et al., 1977; Kelly and Code, 1977) as well as in the present paper. Thus, backward pacing might enhance absorption not only by bringing about more effective stirring of intestinal content because of an increased contractile frequency, but also by slowing transit and prolonging contact of content with the intestinal epithelium.

If similar increases in absorption can be produced by electrical pacing of the intact human bowel, these experiments would point to an intriguing new technique for the treatment of those patients suffering from the serious nutritional, fluid and electrolyte problems of the short bowel syndrome.

An experimental evaluation of segmental reversal after massive small bowel resection

AIRES A. B. BARROS D'SA*

SUMMARY

The technique of reversal of a distal segment of residual small intestine was applied to the management of massive resection. A controlled evaluation was carried out in dogs into the effects of segmental reversal on the proximal remnant after the distal 75 per cent of the small bowel had been resected. The variables studied were survival, body weight, glyceryl tri(palmitate-1-^{14}*C) absorption and mouth-to-caecum transit time. Animals subjected to resection alone had accelerated intestinal transit, poor absorption, serious weight loss and a high early mortality. It was clearly demonstrated that segmental reversal after resection produced marked and progressive delay in transit time from mouth to caecum, sustained improvement in fat absorption and body weight and enhanced survival.*

MASSIVE small bowel resection may be necessary for mesenteric thromboembolic disease, Crohn's disease and trauma (Colcock and Braasch, 1968). Although the operation itself is neither difficult nor exacting, the consequences are serious. While occasional cases of survival after such an extensive ablative procedure have been documented (Kinney et al., 1962), the operation has a high mortality (Simons and Jordan 1969) and the well-recognized short bowel syndrome is common postoperatively. This is characterized by rapid intestinal transit, severe diarrhoea, steatorrhoea, general impairment of absorption and precipitous decline in health. Sequelae such as gastric hypersecretion and accelerated transit are poorly understood but humoral theories have been advanced to explain the mechanism of their occurrence (Wright and Tilson, 1973; Barros D'Sa and Buchanan, 1977).

The diverse pathophysiological problems encountered after massive bowel resection pose great difficulties in management (Barros D'Sa et al., 1978). Despite advances in modern therapy and postoperative care many patients still succumb after massive intestinal resection (Barros D'Sa, 1979) and this has stimulated the experimental trial of several surgical procedures (Budding and Smith, 1967; Sadowski, 1967; Schiller et al., 1968; Hidalgo et al., 1973). The technique of segmental reversal has been tried in the surgical management of the dumping syndrome after gastric resection (Poth, 1957), in treating post-vagotomy diarrhoea (Craft and Venables, 1968), in preventing rapid evacuation after total or partial colectomy (Burrows et al., 1965) and for ileostomy dysfunction (Ellis and Coll, 1968) and even in limiting severe chronic diarrhoea with some success (Madding et al., 1965).

Reversed segments have had minimal clinical trial in the treatment of massive resection and the short bowel syndrome (Hollender et al., 1972). Against a background of conflicting experimental data, Gibson et al. (1962) were the first to apply the procedure successfully in a patient who had undergone extensive bowel resection. While some reports were favourable (Venables et al., 1966; Fink and Olson, 1967), others were inconclusive and lack adequate clinical evaluation (Madding et al., 1965; Blades and Peple, 1970). Of 29 reports, the nutritional results have been satisfactory to excellent in 23 cases (Barros D'Sa, 1975a). Firm evidence of the safety and efficacy of segmental reversal is required before its clinical use can be justified.

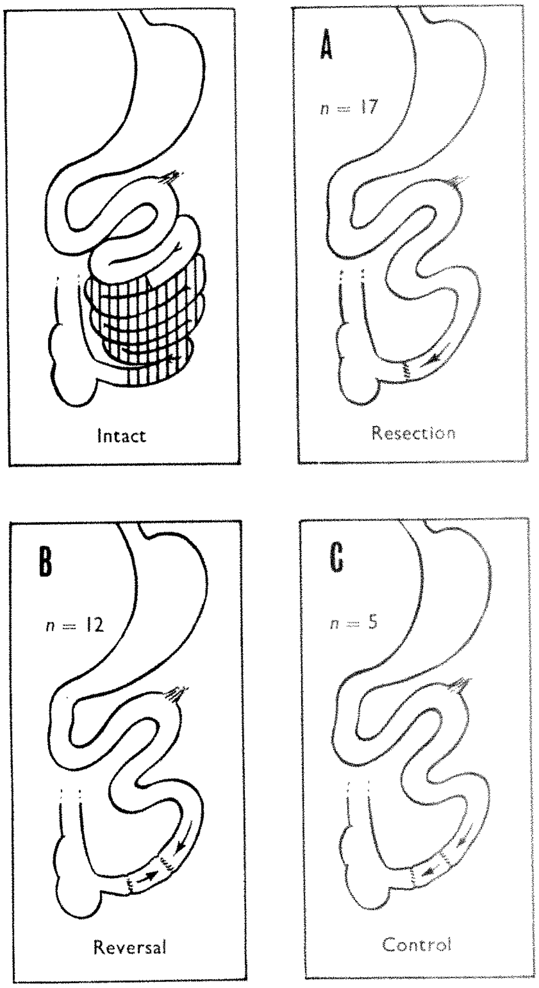

Fig. 1. Experimental models prepared to evaluate the function of reversed segments after massive intestinal resection. The extent of resection is represented by a hatched area.

The objective of this study, therefore, was to carry out a controlled evaluation of the function and usefulness of reversal of a segment in the remnant after massive small bowel resection.

Material and methods

Plan of study

The design of the experiments was as follows. Three dog models, as represented diagrammatically in *Fig.* 1, were prepared and all animals had 75 per cent distal small bowel resections. The first, with resection alone, formed the 'resection' group; the second, with a reversal of the terminal 10 cm of the remnant, formed the 'reversal' group; the third, a specially prepared 'control' group, had the terminal 10 cm isolated and anastomosed without reversal.

The following variables were assessed in these three groups: (*a*) survival after operation; (*b*) body weight before operation and at weekly intervals thereafter; (*c*) fat absorption preoperatively and at intervals after operation, using ^{14}C-labelled glyceryl tripalmitate in the breath analysis technique (the sampling apparatus was modified for use in dogs); (*d*) mouth-to-caecum transit time was measured by radiological screening using a contrast meal before operation and at intervals thereafter.

Due to the number of variables being investigated, (*b*), (*c*) and (*d*) were studied in 7 dogs of the resection group and 7 of the reversal group, all of which were unselected, and in the 5 dogs of the control group. Survival time was recorded in an additional 10 dogs of the resection group and 5 of the reversal group. The results were analysed by comparison of one group with each of the other two using the Student's *t* test.

Material

Registered female greyhounds, aged between 1½ and 2½ years and weighing between 20 and 28 kg, were vaccinated against distemper, cleared of external parasites and wormed. Intravenous Nembutal (pentobarbitone sodium) anaesthesia was employed in a dosage of 26 mg/kg body weight.

The abdomen was opened through a midline incision. Handling of the bowel was avoided before measurement. The ligament of Treitz was identified and the bowel carefully measured along its antimesenteric border, without stretching it, from this point down to the ileocaecal junction using a flexible ruler. The technique allowed reproducible measurements of length to be made. A routine resection of 75 per cent of the distal small bowel was performed, preserving the proximal 25 per cent. A 3-cm length of the ileal stump was also preserved to permit a comfortable end-to-end anastomosis, using a single layer of 3/0 atraumatic chromic catgut with an over-and-over all-coats suture locking every third stitch. This technique was used to prevent, as far as possible, undue invagination or inversion with possible narrowing at the suture line. Any tendency to produce a mechanical impediment to intraluminal flow was thus avoided, a factor of importance in the study. The mesentery was reconstituted. *Fig.* 1(*a*) represents the completed resection group model.

In those dogs that were to have a reversed segment, the terminal 10 cm of the proximal 25 per cent of small bowel was carefully measured along its antimesenteric border after ensuring that this segment was supported by an adequate vascular pedicle. In all cases, a secondary arcade of vessels arising from the primary mesenteric vessels was selected. After resection of the distal 75 per cent of small bowel, transection was effected on a line 10 cm proximal to the end of the remnant, and at this point the mesentery was divided down to the base of the secondary vascular arcades. Employing the mesenteric pedicle as an axis, the 10-cm segment was then rotated through 180° in a clockwise direction so that its proximal end lay opposed to the ileal stump and its distal end to the proximal remnant of the intestine. No occlusion of the blood supply resulted from this manoeuvre. Pulsation in the vascular pedicle and the colour of bowel adjacent to the anastomotic suture were checked before abdominal closure and found to be satisfactory. *Fig.* 2 illustrates the reversed segment *in situ*.

The two anastomoses were performed as described above and the mesenteric defects closed. There was no evidence of ischaemia at the anastomoses. The completed reversal model is illustrated in diagrammatic form in *Fig.* 1(*b*).

In the control group the same technique as adopted in the preparation of the reversal model was used up to the point of transection 10 cm proximal to the tip of the remnant. After that stage, the two anastomoses were carried out without reversing the isolated segment, and the mesentery was left intact. *Fig.* 1(*c*) is a diagrammatic representation of this control model.

The fluid regimen was as follows: 1 litre 5 per cent dextrose/0·5 N saline during the operation; a total of 1·5 litres of 0 5 N saline subcutaneously on each of the first 2 postoperative days; 1 litre 5 per cent dextrose and 0·5 litre N saline intravenously during the day, and 0 5 litre of 0·5 N saline subcutaneously in the evening on the next 3 days. On the sixth postoperative day, oral intake was commenced with milk and water and by the eighth day solid feeding with two 400 g tins of meat ('Lassie Meaty Chunks' Pedigree Petfoods) per day was established. When oral feeding in this quantity was not tolerated by a dog in any group, adequate fluid, caloric and electrolyte needs were provided parenterally, based on the general condition of the animal, the urinary and faecal output and the biochemical analysis of serum electrolytes.

Survival after operation was recorded in the three groups. Animals were weighed preoperatively and at weekly intervals throughout their period of survival; morning fasting weights were recorded.

The breath analysis technique of studying fat absorption by interval sampling of expired air was used (Kaihara and Wagner, 1968). A breath sampler unit was designed with suitable modifications for use with greyhounds. The principle of the device was simply to channel the animal's dried expired air into a breath sampling solution in which CO_2 was 'trapped'. A disposable polythene facemask, fitting comfortably over the dog's head, was attached to the gas inlet of a Ruben (British Oxygen Co. Ltd) non-rebreathing valve allowing the animal to inspire room air freely. The gas outlet of the valve was connected to the drying and trapping section of the apparatus so that all exhaled air ultimately flowed into a sampling vial. This breath sample unit functioned well.

Dogs fasting overnight were weighed. The carrier solution of corn oil was prepared at 5 ml/kg body weight less 20 ml, this being the volume containing the 5 μCi of ^{14}C-labelled fat in the form of glyceryl tri(palmitate-1-^{14}C) (Radiochemical Centre, Amersham). The dose and rinsings with carrier solution were completely ingested. The animals were caged to ensure a resting state and constant metabolic conditions during the test. Eight-hourly breath samples were collected, commencing an hour after giving the dose. Animals accepted the sampler unit and their breathing was steady. Radioactivity in samples was measured and the results of absorbed fat were calculated and expressed as percentage ^{14}C fat dose/mmol CO_2 expired $\times 10^{-4}$.

Mouth-to-caecum transit time was studied radiologically. A standard 250 g of the dog food was used as the test meal. To avoid errors in transit time caused by barium, only 20 g of stable suspension of 95 per cent w/v barium sulphate (Micropaque) were added to the meal which emulsified before administration to fasting dogs. The time of ingestion was noted and the abdomen was screened using an image intensifier to monitor the progress of the meal. The times taken for the head of the food column to arrive at the caecum and for the tail of the column of meal to leave the ileum finally were recorded. Observations were also made of bowel calibre and direction of propulsion of its contents, with particular reference to the behaviour of the reversed segment.

Results

Operation data

The three groups were found to be statistically comparable, the following measurements having been recorded from each animal: (*a*) total length of small bowel, defined as that part between the ligament of Treitz and the ileocaecal junction; (*b*) length of 75 per cent distal small bowel resected; (*c*) length of the jejunal remnant; and (*d*) weight of the gut resected (checked immediately on removal). The two important measurements of length of jejunal remnant and weight of gut resected are plotted in *Fig.* 3.

Survival

The length of survival of individual animals is plotted in *Fig.* 4 and mean survival times are shown.

The resection group had a mean survival time of 21 days and no animal lived for more than 30 days. Survival in the control group was marginally longer with a mean time of 24 days but the difference was not significant. In the reversal group, those dogs that died naturally had a minimum mean survival time of 136 days, no dog dying before 68 days had elapsed. This time is significantly greater than that of either resection or control groups ($P < 0\ 001$). Six healthy animals of the reversal group, clearly in good health, were sacrificed between 213 and 900 days. These 6 dogs, as well as one which was reoperated to remove the reversed segment, together survived to a mean time of 411 days. Taken together, animals in the reversal group survived to a mean of 296 days, which was far greater than that of the control or resection groups. The mean survival time for the reversal group could have been much longer had there been no intervention.

Body weight

All dogs suffered catastrophic weight loss, the amount and rate of weight loss in the resection group being especially high, in spite of fluid replacement, high calorie parenteral nutrition and supplements. Losses in the reversal group were at a consistently lower rate, levelling off before a later gradual weight increase.

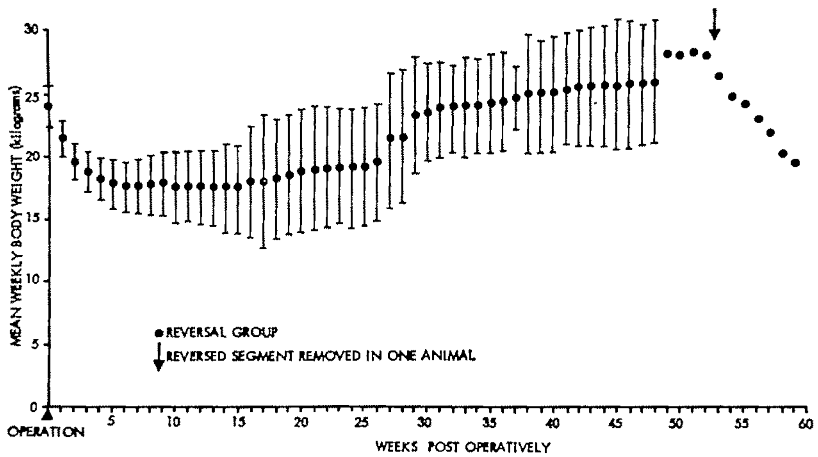

Fig. 6. Mean weekly body weight in reversal group.

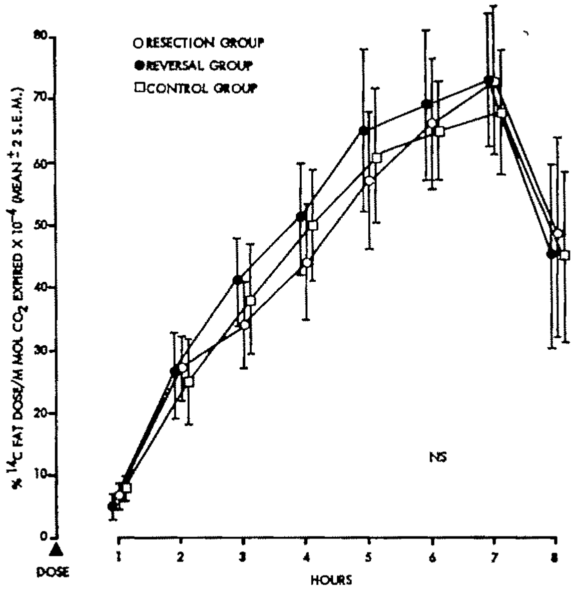

Fig. 7. Glyceryl tri(palmitate-1-^{14}C) absorption. Preoperative results in the three groups.

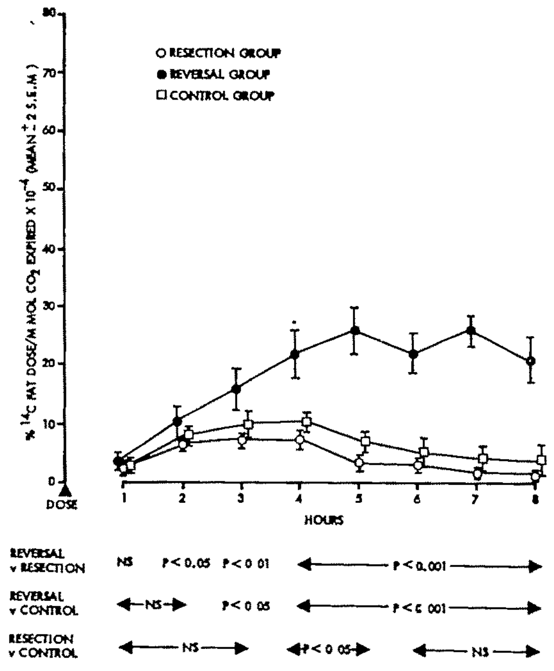

Fig. 8. Glyceryl tri(palmitate-1-^{14}C) absorption. Results in each group 3 weeks postoperatively.

The mean weekly body weights of these groups over the first 5 postoperative weeks give an indication of differential weight loss (*see Fig.* 5). The similar behaviour in the control and resection groups is clearly revealed. The reversal group showed significantly less weight loss than the resection and control groups from the first and second postoperative weeks respectively ($P<0{\cdot}05$ to $P<0{\cdot}01$).

The overall progress of animals in the reversal group can be observed in *Fig.* 6. The greatest mean loss of 6·5 kg occurred at 15 weeks after which there was a steady rise to preoperative levels by 33 weeks. In order to test the value of segmental reversal in accounting for this recovery, the reversed segment in one dog was excised. This particular animal had already exceeded its initial preoperative weight by nearly 1 kg when it was reoperated 1 year later. After reoperation, its weight fell precipitously, a pattern encountered in animals of the resection group.

Glyceryl tri(palmitate-1-^{14}C) absorption

Studies were carried out preoperatively and 3 weeks after operation. As dogs in the reversal group survived, testing was continued at 6, 9, 15, 20, 25, 30, 40 and 50 weeks postoperatively.

The pattern of fat absorption in the three groups before operation is demonstrated in *Fig.* 7. All groups gave comparable results and there were no significant differences between any two groups at each hour of testing. The same animals were then tested 3 weeks postoperatively. The differences in absorption at this stage in relation to preoperative results are striking, and these are illustrated in *Fig.* 8. Marked diminution in absorption was observed in the resection group and the control group behaved similarly, with very low levels recorded after 4 h. Absorption levels in the

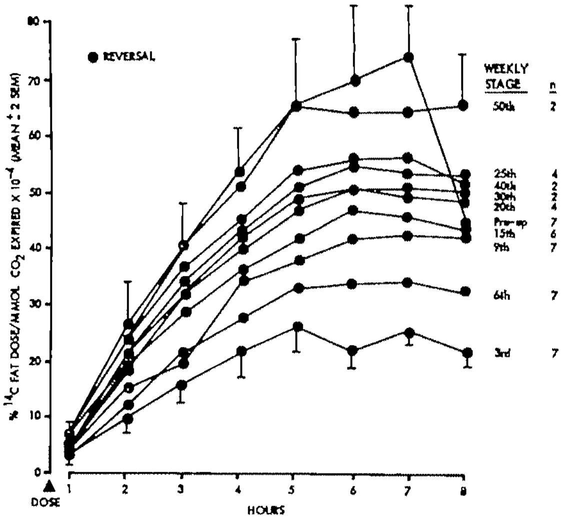

Fig. 9. Glyceryl tri(palmitate-1-^{14}C) absorption. Results preoperatively and at various stages postoperatively in the reversal group.

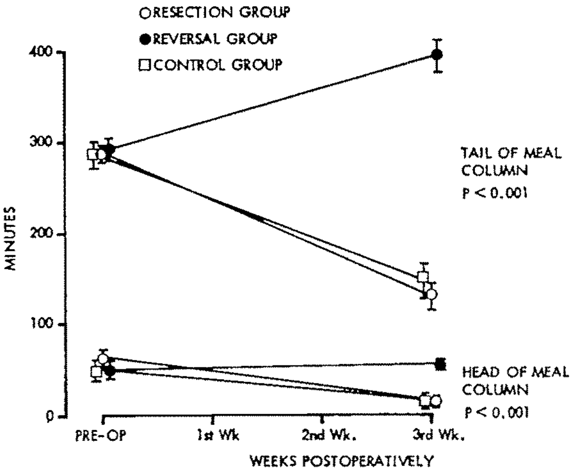

Fig. 10. Mouth-to-caecum transit time. Preoperative and postoperative (third week) results in the three groups.

reversal group also fell well below normal, but these were significantly better than in the resection or control groups, especially after 4 h ($P<0.001$).

Animals of the reversal group survived to be tested repeatedly. An improving ability to absorb fat is clearly demonstrated in *Fig.* 9, this trend progressing with the passage of time. After 15 weeks, absorption levels between 3 and 6 h are comparable to those before operation. After this period, levels remain high, but the number of animals tested was 4, or fewer.

Mouth-to-caecum transit time

These tests were performed preoperatively and 3 weeks after operation. In the reversal group studies were continued at intervals for almost 1 year. Observations of interest during screening were recorded.

The transit rates of the head and tail of the barium column in the three groups are illustrated in *Fig.* 10. *Head of meal column transit time*: All three groups started preoperatively with mean times that were comparable. At 3 weeks after operation, significant falls occurred in the resection group ($P<0.001$) and in the control group ($P<0.01$), but the mean time in the reversal group did not change significantly. However, mean transit time in the reversal group was significantly greater than that of either the resection group or the control group ($P<0.001$).

Tail of meal column transit time: Once again, there was no significant difference among the three groups in the preoperative phase. At 3 weeks the mean transit time in the resection and control groups fell significantly below preoperative values ($P<0.001$), and conversely in the reversal group the mean transit time was longer than preoperative time ($P<0.001$). Quite clearly the mean transit time in the reversal group was significantly longer than that of the resection or control groups ($P<0.001$). It is noteworthy that, in all groups, the alteration in transit rate as a result of operation was greater for the tail than for the head of the meal column.

As several animals in the reversal group survived, further observations of mouth-to-caecum transit times were made at 6, 9, 15, 20, 30, 40 and 50 weeks. The significant delay in transit noted at 3 weeks progressively increased, and at 50 weeks after operation, the mean transit times of the head and tail of the meal column were 50 per cent and 70 per cent respectively above preoperative values.

Observations at screening

Initially, the observed diameters of the jejunal remnant as well as the reversed segment did not suggest dilatation at any stage. In studies done at 40 and 50 weeks, there appeared to be minimal dilatation of the remnant just proximal to the reversed segment, but absence of calibration on the image intensifier made such observations unreliable. Radio-opaque markers placed around each anastomosis permitted a view of motor activity of the reversed segment. There was consistent visual evidence that the reversed segment was physically instrumental in contributing to delay in transit.

As the contrast meal in the jejunal remnant approached and attempted to negotiate the reversed segment, it was halted in the proximal part of the segment distending it. Having shown a reluctance to advance, the meal was promptly squirted back up the jejunal remnant, thus effectively impeding transmission. Distinct repeated and often forceful retrograde flow of the meal was followed by forward propulsion producing a to-and-fro oscillating movement. A little was allowed to pass through into the ileal stump by the reversed segment, so that transit was piecemeal beyond this point. There was no evidence of obstruction in the pathological sense, and the meal emptied slowly into the colon.

Discussion

To be credible, the value of reversed segments must be studied against a picture of severe forms of gut loss. Reports have shown that resections of the order of 75 per cent have been associated with high mortality and morbidity rates (Chen, 1969). A 75 per cent small bowel resection was therefore considered drastic enough to provide a suitable background against which the value of reversed segments could be assessed. The distal rather than proximal small bowel was removed to provide a rigorous challenge in terms of function and survival of the remnant. The ileocaecal valve was preserved to facilitate comparisons of glyceryl tri(palmitate-1-^{14}C) absorption and mouth-to-caecum transit time. Fat absorption is compromised by bacterial contamination from the colon and removal of the valve could have introduced this variable factor (Duret, 1972). Preservation of the ileocaecal valve and caecum further provided a clear end-point in radiological determinations of transit time.

Aspects of technique of segmental reversal have been discussed (Barros D'Sa, 1975a; Leading Article, 1975). A terminal reversed segment would allow maximal exploitation of the potential absorptive capacity of the remnant of bowel proximal to it. By contrast, a proximal segmental reversal may produce hyperacidity (Grundberg et al., 1967). The ideal length for reversal is considered to be within the range of 7·5–14 cm (Leading Article, 1975). Of clinical cases reported in the literature, 27 out of 31 reversed segments used were within the range of 7–15 cm and did not produce any significant complications (Barros D'Sa, 1975a). A third of the segments were 10 cm long, i.e. the length adopted in this study. The technique of Rygick and Nasarov (1969) was found to be impracticable when attempted in a pilot study using 10-cm segments (Barros D'Sa, 1975b). This is not surprising, as their technique utilized 20-cm lengths of bowel, which are excessive.

The control model was prepared in order to incorporate features which conceivably might account for the difference in results between the resection group and the reversal group. These were, first, the extra anastomosis of the reversal model and, secondly, transection of the terminal 10 cm of the remnant which in theory, produces a decreased frequency of the basic electrical rhythm in the isolated segment (Bass and Wiley, 1965).

Estimation of fat absorption after massive resection represents a sensitive index of alimentary function (Wapnick et al., 1969). Faecal fat estimations were open to several sources of error (Bergström and Blomstrand, 1956). As animal survival was being studied, fat absorption methods requiring serial blood sampling were avoided. As glyceryl tri-palmitate is the most common saturated fat in the average diet, glyceryl tri(palmitate-1-^{14}C) absorption by the breath analysis technique provided an adequate test of absorptive function in the experimental models prepared and shows significant correlation with faecal fat excretion (Burrows et al., 1974).

Hammer et al. (1959) first reported improvement in survival of dogs when massive resection was followed by reversing a 1-inch segment of small bowel. While a few other reports of short term beneficial results followed, some of these studies were performed using lengths of segment beyond the optimal range, and therefore not enough confidence can be placed in them (Singleton et al., 1961). Among the limited number of humans treated with reversed segments after resection, 2 patients had survived 7 and 7½ years respectively and were in excellent health (Hollender et al., 1972). In the present study the poor survival figures for the resection group are in keeping with the unsatisfactory results reported in other experimental series and in clinical reports of massive gut loss (Simons and Jordan, 1969). Survival time is clearly enhanced in the reversal group of animals.

Although some experimental workers, such as Repetto et al. (1965), showed that reversed segments diminished weight loss, other workers, including Delaney (1970), failed to observe such benefits. Keller et al. (1965) found that double reversed segments produced more rapid weight gain than when only one segment was used, but that long term survival was not obtained in the former group.

In this study, weight loss after resection was in keeping with observations in man. A review of the literature shows that those few patients who survive extensive resections remain at weight levels well below normal (Barros D'Sa, 1975b). Removal of the reversed segment in one healthy dog proved fatal and probably underlines the continued value of the reversed segment in sustaining life and suggests that adaptation of the remaining intestine is not an important factor in long term survival.

Absorption studies after experimental reversal showed transient improvement in one study using ^{131}I-labelled triolein (Singleton et al., 1961) and gave encouraging results in other studies employing faecal fat estimations (Venables et al., 1966; Depadt et al., 1970). From experiments with reversed segments and other surgical procedures, Delaney (1970) contested these results and stated that absorption was not ameliorated.

The method used in the present study permitted an 8-h quantitative measurement revealing the pattern of absorption. The preoperative peak of fat absorption at 7 h is not seen in subsequent studies in any of the three groups: this flattened curve is largely due to an impaired absorption, most marked in the resection group. It was suggested by Venables et al. (1966) that the prominent wave of peristalsis by the reversed segment permitted two periods of absorption, but such clear peaks were not observed. The consistent rise with time in fat absorption in the reversal group indicates that, regardless of loss of ileum and 75 per cent of bowel length, the remnant, with the aid of the reversed segment, was extremely successful in maintaining nutrition.

In this study transit time measurements excluded transit time through the colon to avoid inaccuracies, especially as dogs have a greater capacity than man for retaining faeces in the colon. Of all techniques for measuring intestinal transit, the radiological screening method afforded simple comparison of results and, of course, an opportunity to visualize the behaviour of the reversed segment.

The action of the reversed segment can best be explained on the basis of the local myenteric reflex (Bülbring, 1961). A schematic representation (*Fig.* 11) may assist in its understanding. A bolus of food entering a normal segment distends it, triggers the submucosal receptors to send an impulse backwards to the muscles which push the bolus forwards. A bolus entering a reversed segment also sends an impulse backwards, in this case distally because the segment is reversed and retains its polarity, thus causing the distal part of the reversed segment to contract and drive the food back up the remnant. Repeated contact of the meal with the mucosa in the remnant is permitted, thus allowing full use to be made of its limited absorptive potential.

The term 'physiological valve' used by Hammer et al. (1959) is inaccurate, and in his experiments using Thiry-Vella fistulas, Holstvgood (1971) confirmed

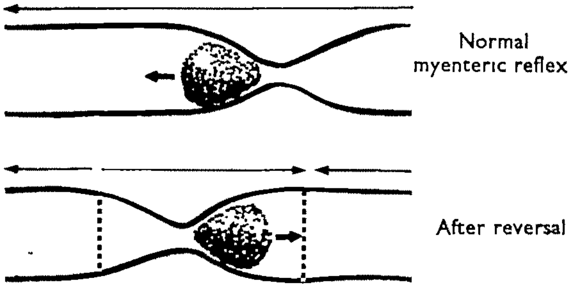

Fig. 11. Suggested mechanism of action of the reversed segment.

that there was no true valvular function. Recent experimental work has shown that levels of certain gastrointestinal hormones are altered not only by massive resection but also by segmental reversal, and this might explain some of the braking action of reversed segments (Barros D'Sa et al., 1975, 1976).

Reversal of the terminal segment of the remnant of jejunum after 75 per cent distal small bowel resection produces marked and progressive delay in intestinal transit time. This fits in well with sustained improvement in fat absorption, and, in turn, correlates well with weight status and enhanced survival. This contrasts markedly with both the resection and control groups which in all respects resemble each other. The possibility that either transection or the extra anastomosis necessary in fashioning a reversed segment may have been responsible for improvement in all parameters is therefore eliminated.

One question has to be raised. How much of the success of reversal can be ascribed to intestinal adaptation? While some adaptation might have occurred, general experience in animals and man shows that there is considerable individual variation in tolerance of massive resection and the capacity to adapt sufficiently to decrease morbidity and mortality. In the reversal group all animals showed significant and early improvement, while those in other groups universally exhibited relentless deterioration, and it is therefore unlikely that adaptation contributes significantly to the striking results, as illustrated by the outcome of removing the reversed segment in one healthy dog.

In conclusion, these studies demonstrate in greyhound dogs the beneficial effect of reversal of a 10-cm segment of bowel at the distal end of the remaining small intestine after the distal 75 per cent of the small bowel has been resected leaving the ileocaecal valve intact. It seems reasonable to apply these findings to the care of people who have severe intestinal insufficiency as a result of massive resection of small intestine.

Use of circular stapling gun with peranal insertion of anorectal purse-string suture for construction of very low colorectal or colo-anal anastomoses

J. C. GOLIGHER*

SUMMARY

A technique is described for construction of the colorectal or colo-anal anastomosis in low rectal resection by using an automatic circular stapling device and inserting the anorectal purse-string suture peranally from below. This method was employed in 4 patients resulting in complete healing in 3 cases and a moderate leak in 1, which, however, eventually healed satisfactorily.

We have described our initial encouraging experiences with the new Russian circular stapling gun for the construction of colorectal anastomoses in anterior resection (Goligher et al., 1979). One of the advantages of this device is that an anastomosis can be achieved at a lower level than would be feasible with hand-placed sutures. Thus it has been possible with its aid to extend the range of anterior resection. A sphincter-saving resection by abdomino-anal pullthrough, abdomino-transanal, abdomino-sacral or abdomino-transsphincteric techniques has still to be considered for lower carcinomas of the middle third of the colon.

These different operative methods have their respective advantages and disadvantages and the choice between them is a very personal one for the individual surgeon. Currently the abdomino-transanal technique of Parks (1972) is attracting a good deal of attention in Britain. It involves a very low resection from the abdominal aspect, leaving a small anorectal remnant comprising little more than the anal canal. Continuity of the intestinal tract is restored by a sutured anastomosis between the colon stump and the anorectal remnant, conducted from below through the anus opened up by a bivalve anal retractor. For this purpose Parks (1972) originally used a single row of interrupted end-to-end sutures between the cut lower edge of the colon stump and the cut upper edge of the anorectal stump, just at or immediately above or below the anorectal ring. More recently, however (Parks and Thomson, 1977), Parks has favoured a technique which provides for 'coring out' the mucosa of the anorectal remnant from the underlying internal sphincter and circular muscle coat, starting 0·5–1·0 cm above the pectinate line and working up to the top edge of the remnant. The colon stump is then drawn down through the denuded anal canal. It is fixed by a few sutures passed between its serosal surface and the upper edge of the muscle coat of the anorectal remnant, and then its cut lower edge is sutured to the anal mucosa just above the pectinate line by a circumferential series of interrupted 2/0 Dexon sutures that also include some of the internal sphincter in their bite. Parks and Thomson (1977) believe that this type of imbricated or sleeve anastomosis is more secure than an ordinary end-to-end suture.

Recently the present author has found that the construction of a simple end-to-end colo-anal or colorectal anastomosis in abdomino-transanal resection can be greatly facilitated by using the circular stapling gun in the same way as it is employed in anterior resection, except that the purse-string suture in the top of the anorectal stump is inserted not from the abdominal aspect, but from below through the anal canal held open by a bivalve speculum.

Technique

The operation is conducted with the patient in the lithotomy-Trendelenburg position (Lloyd-Davies, 1939), which gives simultaneous access to the abdomen and anal region. The carcinomatous segment of rectum and most of the sigmoid are resected in the usual way, a distal margin of clearance of 4–5 cm being secured. Both the rectal and colonic stumps are controlled by crushing Parker–Kerr clamps. In due course these will be removed by excising them from the bowel; purse-string sutures will then be inserted in the ends of both stumps. However, it is best to leave the clamp on the colon stump till the purse-string has been placed in the rectal stump, otherwise troublesome faecal leakage from the colon may take place whilst the latter manoeuvre is being carried out.

Insertion of purse-string suture in superior edge of anorectal stump per anum

A bivalve speculum capable of wide separation of its blades, such as the larger version of the author's own retractor (made by C. F. Thackray, Park Street, Leeds) or of Parks's retractor, is introduced into the anal canal and opened to its fullest extent. The third blade is then inserted to improve the access still further. By this means a good view is obtained of the interior of the posterior wall of the anorectal remnant up to its superior edge. The purse-string suture of 2/0 monofilament Prolene or well-waxed fine linen thread, which is going to be placed along the upper edge, is started in the midline posteriorly, being passed from the mucosal aspect outwards through the rectal wall about 4 mm from the cut edge (*Fig.* 1). The stitch is continued to the patient's right with a series of similar bites of the needle from within outwards at intervals of 4 mm along the top of the anorectal stump and 4 mm from the cut edge. When the right margin of the exposed sector of anorectal wall is reached, the retractor is rotated in a clockwise direction through 90 degrees and the stitch is continued along the top edge of that sector. By further rotations in due course the anterior and left lateral sectors are similarly exposed for suture, till finally the posterior sector is again exposed and the suture reaches its starting point (*Fig.* 1). The suture is not at this stage tightened or tied, but the ends are left long and emerge through the anus.

Introduction of suture gun and tying of anorectal purse-string suture on central shaft

There are two ways in which the purse-string suture thus inserted into the top of the anorectal stump can be tied on the central shaft of the suture gun. By one method it is done entirely from below. The third blade of the retractor is now removed and the amount of separation of the other two blades slightly reduced. The suture gun is then lubricated, opened to the maximum extent and introduced through the anal canal into the pelvis, sufficiently far to take the head end above the upper edge of the anorectal stump, whilst the central shaft lies in the anal canal itself and the shoulder-piece is still below the anal verge (*Fig.* 2). The anal retractor is next withdrawn

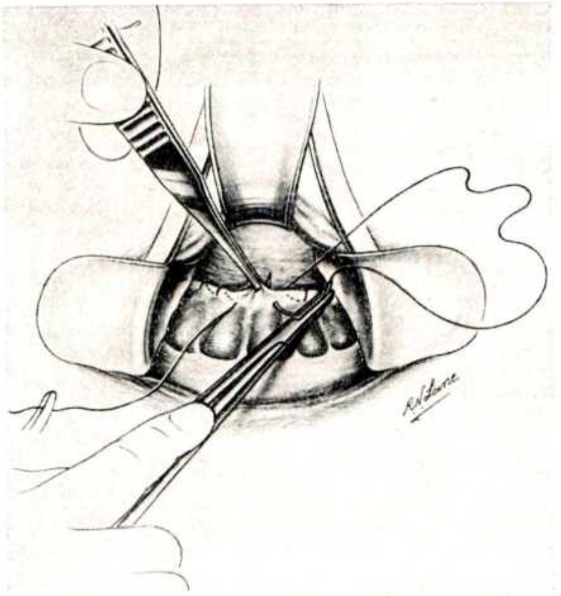

Fig. 1. View obtained of interior of anorectal remnant with anal speculum in position. The 2/0 monofilament Prolene suture has been inserted along the top of the remnant starting in the midline posteriorly and continuing as an over-and-over stitch from inside the lumen 4 mm or so from the cut edge, the retractor having been rotated to expose each sector of the bowel in turn. The stitch has now reached the posterior sector again and is approaching the starting point.

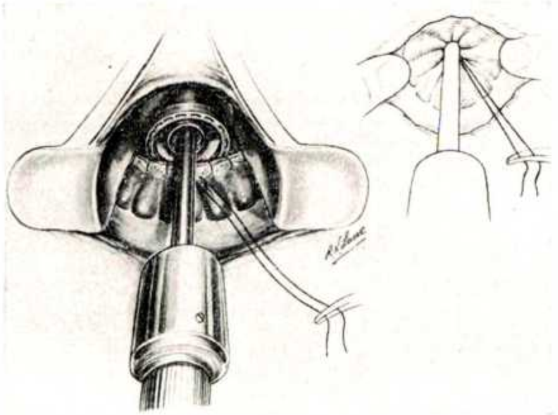

Fig. 2. The third blade of the anal retractor has been removed and the separation of the other two blades reduced somewhat, whilst the head end of the opened suture gun is inserted through the anal canal to beyond the top of the anorectal remnant. (Inset) The anal retractor has been removed and the anorectal purse-string suture has been tied from below on the central shaft.

completely and the tails of the purse-string suture on the top of the anorectal stump are tied firmly on the central shaft, the knotting being assisted by the points of the two index figures being passed up inside the anal canal (*Fig.* 2 inset).

The alternative, and usually preferable, way of tying the anorectal purse-string suture is to do so from above. In this technique the tails of the loosely placed suture which project through the anus are clipped at their ends with a long artery forceps and passed up through the anal canal to be grasped by the abdominal operator using a similar pair of long forceps passed down into the pelvis. The perineal operator releases his

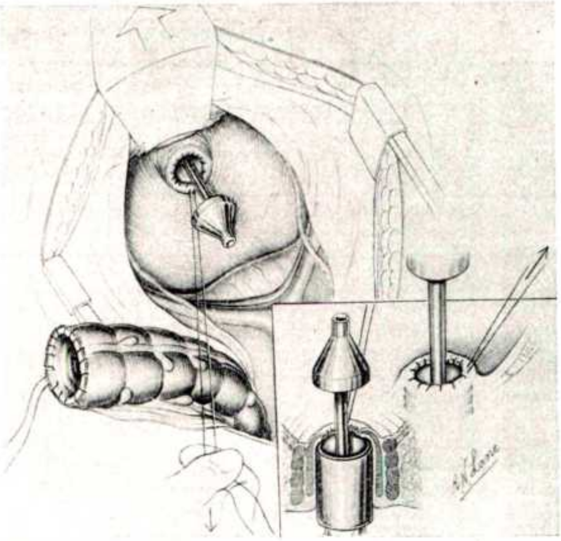

Fig. 3. Alternative method of tying anorectal purse-string suture from above. The tails of the suture have been passed up through the anal canal to the abdominal operator. Whilst the bladder and prostate are retracted strongly forwards to expose the top of the anorectal remnant held up by the purse-string suture, the suture gun is inserted from below by an assistant and opened to carry the head into the pelvis beyond the edge of the anorectal stump, whilst the distal edge of the shoulder-piece still lies in the remnant (*see* inset). The purse-string suture is then tied on the central shaft just above the shoulder-piece.

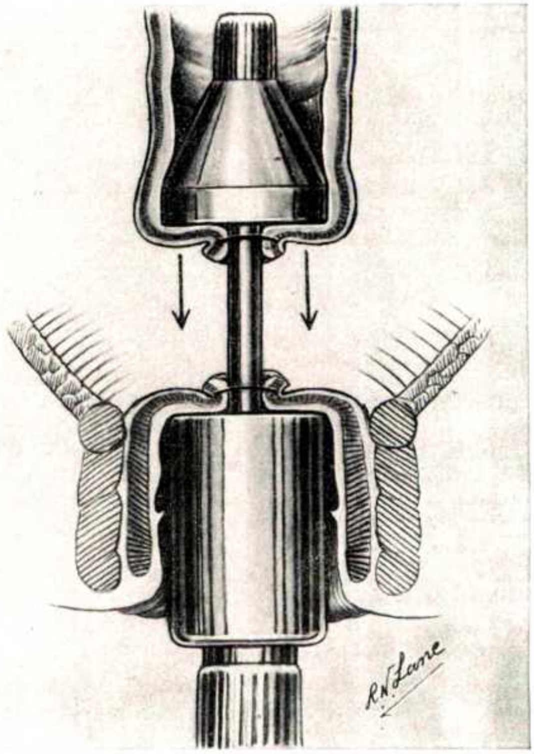

Fig. 4. Diagrammatic view of the 'opened' suture gun in position with the purse-string sutures in both anorectal and colonic stumps tied and the instrument about to be 'closed' preparatory to 'firing' the staples.

hold on the suture, the tails of which are then drawn up into the abdominal field. The bladder, seminal vesicles and prostate (or uterus and vagina) are now retracted strongly forwards by the abdominal operator to display the top of the anorectal remnant held up by traction on the ends of its purse-string suture (*Fig*. 3). The perineal assistant has meanwhile removed the bivalve anal speculum and introduced the lubricated closed suture gun into the anal canal. As soon as the tip of the conical head is seen emerging through the top of the stump by the abdominal surgeon, the gun is 'opened' by the perineal operator to advance the head-piece into the pelvis 4–5 cm beyond the cut edge of the anorectal remnant, whilst the shoulder-piece is still in the anal canal just below the purse-string suture (*Fig*. 3. inset). The suture is then tied firmly on the central shaft immediately above the shoulder-piece.

Advancement of gun in anal canal and fastening of colon stump

With the first method of tying the anorectal purse-string suture from below, the shoulder-piece of the gun does not at this stage lie properly in the anal canal. Accordingly the gun is now advanced gently so that the edge of the shoulder-piece proceeds up the anorectal remnant as far as the purse-string suture on its upper end will allow. With the second method of tying the anorectal purse-string suture from above the shoulder-piece is already in this position (*Fig*. 4). The abdominal surgeon then takes the end of the colon stump, into which a purse-string suture of 2/0 monofilament Prolene has already been loosely inserted, and slips it over the conical head of the gun, the purse-string suture being immediately tied on the central shaft to hold the bowel in place (*Fig*. 4).

Closing and 'firing' of gun

By clockwise rotation of the wheel on the proximal end of the barrel of the gun the head and shoulder-pieces are gradually opposed till the gap between these two parts is reduced to 1·5–2·0 mm. The gun is then 'fired' by approximating the two limbs of the handle with a sudden sharp movement, the effect being to drive the staples through the compressed tissues of the colonic and rectal walls and at the same time to cut through these walls with the circular trephine knife just internal to the staple line.

Extraction of gun

By winding the wheel in an anticlockwise direction the head and shoulder-piece are separated sufficiently to release the stapled flange of bowel wall and the instrument is gently extricated from the bowel, leaving a colorectal or coloanal anastomosis at or just above the anorectal ring (*Fig*. 5).

Results

So far this technique of inserting the anorectal purse-string suture from below through the anal canal has been employed in only 4 patients. All were men and all had rectal carcinomas at 8·0, 8·0, 8·5 and 9·0 cm respectively from the anal verge on preoperative sigmoidoscopic examination; 2 of the men were decidedly obese. The placing and tying of the anorectal purse-string suture was certainly easier than inserting sutures directly between the colonic and anorectal stump by either of the techniques described by Parks (1972) and Parks and Thomson (1977). Radiological studies after Gastrografin enemas, as described in previous publications (Goligher, Graham et al., 1970; Goligher, Morris et al., 1970; Goligher et al., 1977) were conducted on all 4 patients, but the opaque medium was injected not per anus as an enema for fear of injuring the anastomotic line with the rectal tube, but through the distal opening of the covering transverse colostomy that was established in all these cases. In one case a moderate anastomotic dehiscence was revealed but it subsequently healed satisfactorily and the patient did well. In all the other cases the anastomoses were intact. The sigmoidoscopic heights of the anastomoses were 5·0, 4·5 (2 cases) and 4·0 cm.

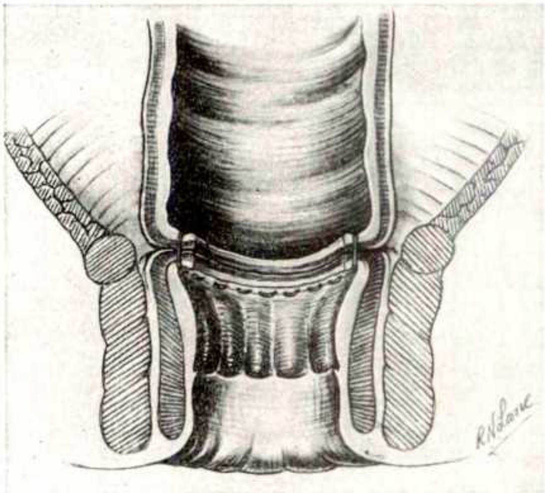

Fig. 5. A diagrammatic representation of the stapled anastomosis at or just above the anorectal ring after withdrawal of the gun.

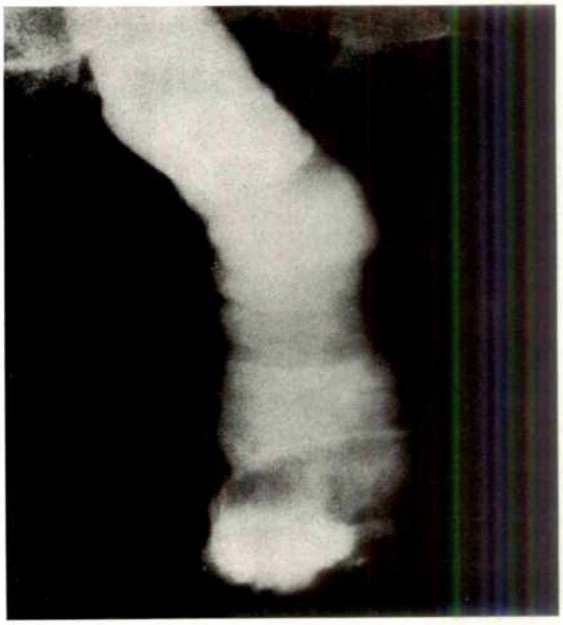

Fig. 6. Radiological examination after Gastrografin enema in a man treated by abdomino-transanal resection using the circular stapling gun for construction of the anastomosis. The staples indicate the site of the very low anastomosis, which is intact, just above the anorectal ring.

In 3 patients the covering transverse colostomy was closed after 2 months. When the faecal flow was at first restored to the anal canal there was a greatly increased frequency of defaecation with as many as 12–15 calls to stool per day and a good deal of incontinence for flatus and faeces. Gradually the frequency became less and the control better, and 2 of the 3 patients are now fully continent 5 and 7 months after closure of the colostomy but still have bowel actions at least 4–7 times daily. The third patient, who had his colostomy closed 3 months ago, is still not completely continent but his function is improving. The fourth patient, whose operation was performed only 6 weeks ago, still retains his colostomy.

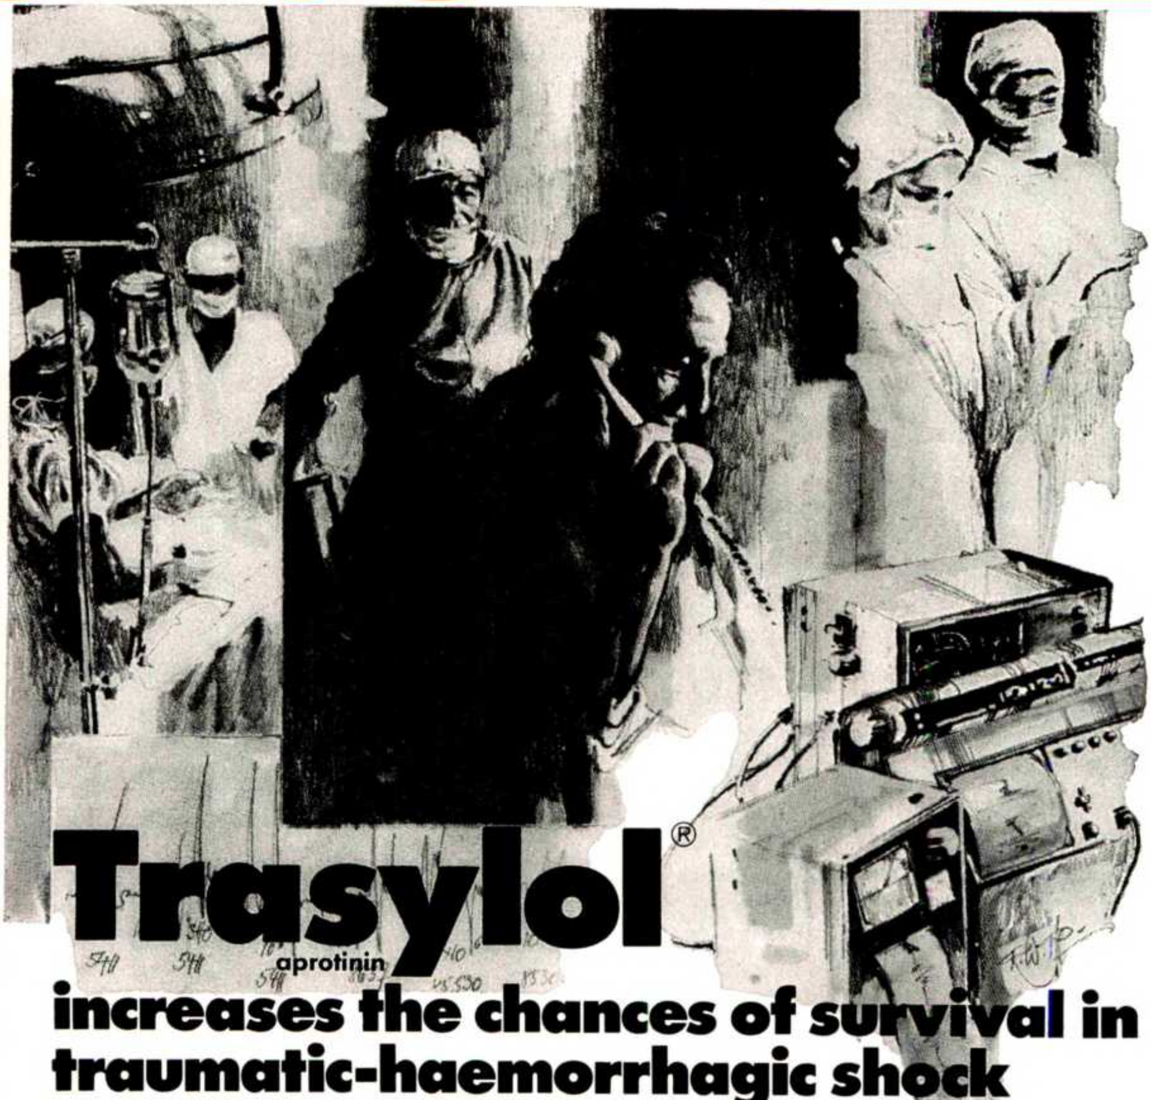
SHOCK



Trasylol®
aprotinin

increases the chances of survival in traumatic-haemorrhagic shock

The results of a large German field study[1]: Marked reduction of mortality when Trasylol was applied early. Precise clinical investigations in 70 shock patients by an Australian double-blind study[2]) provided an explanation and further proof for the effectiveness of Trasylol in shock: With Trasylol development of post-traumatic respiratory insufficiency (shocklung) was less frequent.

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short-term infusion (5 ml/min to the patient in the recumbent position); thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU*

Transcutaneous defunctioning colostomy

FERNANDO REÑAGA SYKES*

SUMMARY

The technique is described for constructing an occlusive tube colostomy which requires no second operative procedure for closure. The advantages of this method are discussed and it is recommended as a superior alternative to loop colostomy or caecostomy for defunctioning the unobstructed distal bowel.

DIVERSION of the faecal stream to defunction the distal colon presents technical problems; the two most important are, that the diversion of the faecal stream is frequently incomplete and that a second operation is required to close the colostomy. The aim of this paper is to describe a technique which overcomes these problems.

Method

The part of the colon selected for the colostomy is brought out through the omentum so that the omentum shields the remaining abdominal cavity from faecal contamination. A soft Penrose drain 2–3 cm wide and 20 cm long is passed through the mesocolon near the bowel wall. Three centimetres proximal to the Penrose drain and on the antimesenteric border of the colon, preferably through a taenia coli, a longitudinal incision 2 cm long is made. A de Pezzer catheter, with the side holes enlarged, is passed into the lumen of the bowel through the incision (*Fig.* 1). A purse-string suture is placed around the catheter to avoid spillage. The de Pezzer catheter is invaginated into the wall of the colon by suturing the serosa over the catheter for a distance of 8–10 cm. Two skin incisions 3 cm long are made parallel to the colon at the site of the Penrose drain, each end of which is brought out through an incision. A third incision is made for the de Pezzer catheter, between those for the Penrose drain and the laparotomy wound (*Fig.* 2).

The ends of the Penrose drain are tied over a gauze swab, ensuring that the lumen of the colon is occluded against the abdominal wall without impairing the blood supply. The tip of the de Pezzer catheter now lies free in the proximal colon with the distal end occluded by the Penrose drain. Having ascertained that the de Pezzer catheter is suitably sited, it is sutured to the abdominal wall.

On completion of the transcutaneous defunctioning colostomy, the laparotomy incision is closed. Anal dilatation is a routine procedure following this operation.

Postoperatively the catheter is attached to tubing, and washouts through the catheter are only performed if there is a suspicion of tube blockage. In order to remove the tube, which is left in place for a minimum of 3 weeks, one end of the Penrose drain is divided (*Fig.* 3) and the drain is withdrawn. The de Pezzer tube is then removed and normal gastrointestinal continuity restored without a further operative procedure. Barium enema studies performed after removal of the drain show a narrowing at the site of the colostomy; however, a repeat examination at 1 year shows a normal colonic lumen.

Discussion

To date, 12 transcutaneous defunctioning colostomies have been performed (low rectal anastomosis, 10; traumatic faecal fistula in the sigmoid, 1; sigmoid myotomy, 1). The only complication in this series occurred in the first patient whose catheter was removed on day 14 after operation; this resulted in leakage along the catheter track causing an abscess. This was aggravated by the passage of the catheter through the upper end of the laparotomy wound. For

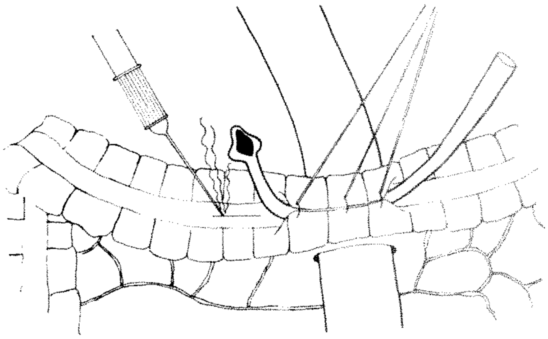

Fig. 1. The Penrose drain has been placed through the mesentery and the incision in the taenia coli of the antimesenteric border is being made. Note the enlarged opening in the tip of the de Pezzer catheter.

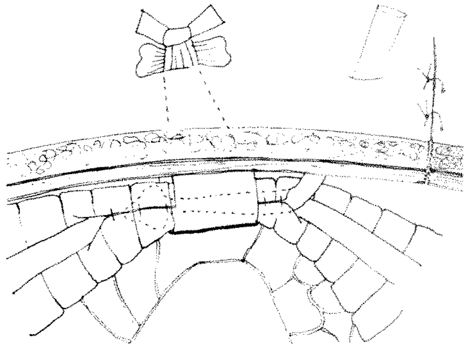

Fig. 2. The completed operation. The Penrose drain has been tied over a gauze swab, and the tube drain brought out through a separate incision between the Penrose drain and the abdominal wound.

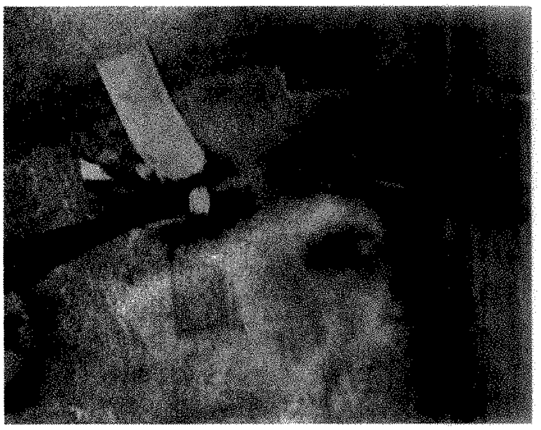

Fig. 3. Removal of the transcutaneous colostomy: the Penrose drain is being divided on the skin surface in preparation for removal.

---

* Head of the Proctology Department, Surgical Unit, Hospital Sagrado Corazón, Barcelona, Spain.

this reason a separate incision was made in the remaining cases.

The indications for this procedure are indentical to those of the usual loop colostomy, but in the presence of complete obstruction distal to the colostomy, the dangers associated with a closed loop would occur. Even in the presence of partial obstruction, this colostomy would not enable complete clearance of the faecal contents of the bowel immediately proximal to the obstruction, hence, it would not be advised in the management of obstruction.

However, the place of this procedure is in those instances when complete rest of the distal colon is required, such as in the presence of a faecal fistula. For defunctioning the colon in order to protect an anastomosis it is ideal, producing a complete exclusion, yet not requiring a second operation to clear the colostomy. Because the faeces drain through a tube into a bag, the patient is spared the discomfort of a colostomy, which, particularly in the immediate postoperative period, is hard to manage. The emotional stress to which many patients are submitted by the appearance of a colostomy is avoided by this technique and the inevitable odour is reduced by the closed drainage technique described.

The technique of transcutaneous defunctioning colostomy is proposed as an alternative to both loop colostomy and a caecostomy, overcoming the disadvantages of both techniques and having few, if any, drawbacks of its own.

Pyloromyotomy forceps

A. G. JOHNSON AND F. KHAN*

A NUMBER of different instruments have been devised for performing pyloromyotomy (Ramstedt's operation) in infants (Quinby, 1966; Benson, 1969). The best known is the Dennis Browne forceps (Browne, 1951), but this is only useful at the end of the operation when the muscle has been well separated, because its tips are 3 mm apart when closed. Many surgeons insert a small curved haemostat into the scalpel incision to separate the circular muscle fibres, but this is often too wide and is smooth on the outside and tends to slip. The new forceps (GU Manufacturing Co. Ltd, Plympton Street, London) illustrated in *Fig.* 1 is serrated on the *outside* and closes to form a sharp 'keel' (*inset*) which can be inserted into the initial scalpel incision. The curve of the blades follows the shape of the pyloric muscle in longitudinal section and the tip is blunt so as not to damage the thin fornix of the duodenal wall at the end of the incision. For the past 3 years the forceps has been found useful by more experienced surgeons as well as by registrars learning the operation for the first time.

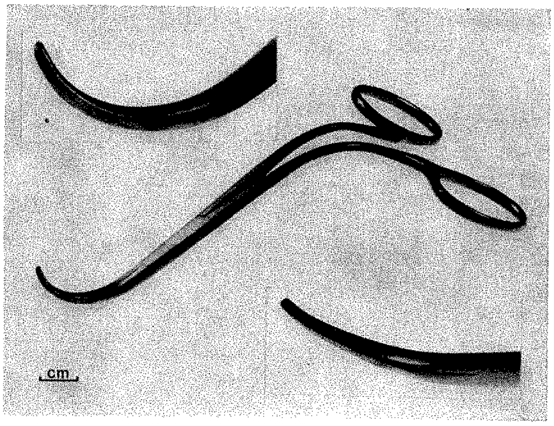

Fig. 1. The forceps, with close-up views of the tips.

The effect of levamisole on postoperative immunosuppression

R. WINDLE, R. F. M. WOOD AND P. R. F. BELL*

SUMMARY

Cell mediated immunity was studied before and after surgery in patients with colorectal cancer. Thymus-derived (T) lymphocytes were enumerated and their non-specific activity was measured by assessing phytohaemagglutinin (PHA)-induced blastogenesis. Specific T lymphocyte activity was measured by leucocyte migration inhibition in response to purified protein derivative of tuberculin (PPD) and autochthonous tumour extract. One group of patients received levamisole postoperatively and the other group consisted of controls. There was a more rapid return to preoperative levels of leucocyte migration inhibition to both antigens by the levamisole group. However, levamisole administration had only a marginal effect on the postoperative depression of cell counts and did not restore depressed lymphoblast transformation.

FOLLOWING surgery there is a depression of cell mediated immunity. This has been demonstrated by a reduction in the numbers of circulating thymus-derived (T) lymphocytes (Miller et al., 1976). In addition, lymphoblast transformation in response to phytohaemagglutinin (PHA) (Riddle and Berenbaum, 1967; Park et al., 1971) and leucocyte migration inhibition (Cochran et al., 1972) are both depressed after operation.

Intraoperative manipulation of a malignant lesion may cause dissemination of cells. A reduction in cell mediated immunity at such a time could therefore detrimentally affect prognosis.

Levamisole, an anthelmintic agent, has been shown to restore cell mediated immunity depressed by age (Verhaegen et al., 1973) or cancer (Tripodi et al., 1973). The effect of levamisole on cell mediated immunity depressed following surgery has not to our knowledge been reported.

We have investigated cell mediated immunity before and after surgery for colorectal cancer and have assessed the effect of the postoperative administration of levamisole.

Cell mediated immunity was studied using three techniques:

1. Enumeration of T lymphocytes.
2. The leucocyte migration inhibition test in response to purified protein derivative of tuberculin (PPD) and autochthonous tumour.
3. The degree of blastogenesis in response to phytohaemagglutinin (PHA).

Patients and methods

Two groups of 10 patients with colorectal cancer were studied. One group of patients received 50 mg of levamisole three times per day orally on the first 3 postoperative days. The other group of patients acted as controls and were not given levamisole. The groups were age-matched with 8 males and 2 females in each group. In 7 patients in each group the tumour was confined to the bowel and a curative resection was performed. Three patients in each group had extensive disease with lymph node involvement or distant metastases. Of these 6 patients, 4 had a palliative resection and 1 patient in each group was inoperable and underwent colostomy alone. Anaesthesia and medication were identical for both groups with the exception of blood transfusion. Four control and 6 levamisole patients were transfused during surgery. Blood was taken for immunological assessment immediately before surgery and at 3 and 7 days after operation for T cell estimation, and at 1, 14 and 28 days after operation for the tests of lymphocyte function. Further tests were performed at 2 months, if there was persistent immunosuppression.

Immunological assessment

Enumeration of lymphocytes: A total white cell count was performed and lymphocytes were enumerated by a differential white cell count on a Giemsa-stained, air-dried blood film. T cells were enumerated by assessing E rosette formation by the method of Strong et al. (1975). Heparinized blood was centrifuged on a Ficoll–Hypaque gradient and lymphocytes at the interphase were collected, washed in Hanks' solution and counted. Next, 100 µl of lymphocyte suspension with 4×10^6 cells/ml were mixed with 100 µl of heat-inactivated fetal calf serum and 100 µl of 0·5 per cent sheep red cells. The mixture was incubated at 37 °C for 1 h, centrifuged at 200 *g* for 5 min and finally refrigerated at 4 °C for 16 h. The cell button was resuspended by gentle tapping of the tube. The proportion of lymphocytes without rosettes and of lymphocytes with three or more attached sheep red cells was assessed. One hundred rosettes were counted and each experiment was performed in quadruplicate.

Pre- and postoperative results were compared using the Wilcoxon matched pairs signed ranks test and have been expressed as counts ±one standard error.

Antigenic extracts: Extracts rich in large membranous cell fragments were prepared for each patient from normal colonic mucosa taken at least 10 cm from the tumour site and from a portion of the resected tumour using a modification of the method of Jones and Turnbull (1975). The homogenized tumour was centrifuged at 1000 *g* and an aliquot was removed and subjected to further centrifugation at 3000 *g*. The residue was resuspended in half the volume of supernatant. The protein concentration of this suspension was measured using a ultraviolet spectrophotometer and the specimen was stored at −20 °C for use as antigen in the leucocyte migration inhibition test.

Leucocyte migration inhibition test: The method used was that of Søborg and Bendixen (1967). The patient's cells were migrated in plastic wells containing medium alone for controls and medium containing PPD (200 µg/ml) to test tuberculin sensitivity. To test tumour-directed cell mediated immunity the wells were filled with medium containing either normal colonic extract or colonic tumour extract. The tumour extract was used at the maximum concentration which had been shown to be non-inhibitory to the migration of leucocytes from a normal patient. This was 100 µg/ml for each patient. The medium used was Eagles MEM with 10 per cent fetal calf serum. Six wells were used for each test and after incubation at 37 °C for 16 h the migration areas were drawn using a microscope with a camera lucida attachment. The areas were then measured by planimetry.

Significant migration inhibition was assessed by the Mann–Whitney U test of ranking. The results have been expressed as the number of patients in each group who, following surgery, had a leucocyte migration inhibition test significantly depressed below that found preoperatively. Comparison between the rates of return of the treatment groups was also made using the Mann–Whitney U test.

Patients	No depression following surgery	Days 3	7	14	28	>28
Controls (n = 10)	1	7	6	4	3	0
Levamisole (n = 10)	0	10	9	6	2	0

Lymphocyte blastogenesis: The method used was a modification of that described by Luquetti and Janossy (1976). Heparinized whole blood was diluted 1 in 10 with medium 199. Aliquots of 200 μl of the mixture were placed in separate wells of a multiple culture plate and to each was added either 0·5 μg of purified PHA or an equal volume of phosphate-buffered saline. Culture plates were sealed and incubated for 24 h in 5 per cent CO$_2$ at 37 °C. Following incubation the cultures were labelled with 0·5 μCi of tritiated thymidine and were harvested using a multiple sample harvester following incubation for a further 24 h. The activity of the samples was then determined by liquid scintillation counting.

Results have been expressed as the number of patients who, following surgery, demonstrated a significant depression of thymidine uptake (lymphocyte responsiveness) below that obtained preoperatively. Significance has been assessed by comparing postoperative results with those obtained before surgery using the Wilcoxon matched pairs signed ranks test.

Results

Lymphocyte and E rosette counts

There was a depression of both total lymphocyte and E rosette counts 3 days following surgery in both groups. This reached significance ($P<0{\cdot}05$) in the untreated patients. The counts increased again towards preoperative levels at 7 days. The results are detailed in *Tables I* and *II*.

Leucocyte migration inhibition test

Before surgery 9 control patients and 8 levamisole-treated patients demonstrated leucocyte migration inhibition to PPD. Extract of the patients' own tumour produced migration inhibition in 4 patients in the control group and in 3 patients in the levamisole group. In all patients with positive preoperative tests, these became negative on the first postoperative day. *Tables III* and *IV* express the number of patients in each group with depressed leucocyte migration inhibition on each test day following surgery.

There is a significant difference between the return of migration inhibition of control patients and the levamisole-treated patients for both PPD ($P<0{\cdot}001$) and tumour extract ($P<0{\cdot}05$).

Lymphocyte blastogenesis

There was a depression in the response to PHA, with all but one patient showing a significant fall after operation. The return to preoperative levels was variable in both groups, but when compared with the control patients, levamisole failed to produce a more rapid return to normal. The detailed results are shown in *Table V*.

Discussion

The presence of cell mediated immune depression in cancer patients is associated with a poor prognosis (Eilber et al., 1975). Correction of immune depression by the immunostimulant levamisole has been shown to improve the prognosis of advanced breast cancer (Rojas et al., 1976) and melanoma (Wilkins and Olkowski, 1977).

Riddle and Berenbaum (1967) have shown that surgery causes immunosuppression. This occurs during the period when cancer cells, dissipated by surgical manipulation, may be developing into metastatic foci. The correction of immunosuppression following surgery may help to prevent this problem. In this study an attempt has been made to reduce the degree and duration of immunosuppression following surgery by the use of levamisole. In immunosuppressed patients, levamisole has been found to restore delayed hypersensitivity (Tripodi et al., 1973) and to increase leucocyte migration inhibition to specific antigens (Goebel et al., 1977). T lymphocytes and their response to mitogens have also been shown to be augmented by the use of levamisole *in vivo* (Renoux et al., 1977).

Both lymphocyte and E rosette counts were depressed on the third postoperative day in the untreated group of patients. The levamisole-treated patients also demonstrated depressed cell counts at 3 days. The finding that the results did not reach significance in the levamisole group could be accounted for by the larger error in this patient group. By the seventh postoperative day there was a return to preoperative cell counts in both groups. The difference between the postoperative depression of lymphocyte

NOW
FLAGYL
METRONIDAZOLE
INJECTION
FOR INTRAVENOUS INFUSION

**proves decisive
in anaerobic
infections**

Only with recent improvements in bacterial culturing techniques has the pathogenic role of anaerobes in post-surgical infections been fully recognized.[1-3] Now 'Flagyl' injection offers you a decisive means of treating these infections – which are often life-threatening and often resistant to established antimicrobials. The response to 'Flagyl' injection is rapid and dependable,[2] as it is consistently bactericidal to pathogenic anaerobes at tissue concentrations easily achieved in treatment. Bacterial resistance is not a problem,[2,4] and 'Flagyl' is highly acceptable – as eighteen years of use in other indications has established.

Treatment: adults and children over 12 years: 100 ml by intravenous infusion eight hourly, administered 5 ml per minute. Oral medication with 400 mg three times daily should be substituted as soon as this becomes feasible. Treatment for seven days should be satisfactory in most cases. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 7.5 mg per kg bodyweight. Prevention: adults and children over 12 years: 100 ml by intravenous infusion immediately before, during or after operation, followed by the same dose eight-hourly until oral medication (200 to 400 mg three times daily) can be given to complete a seven-day course. Children under 12 years: as for adults but the single intravenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight and the oral dose on 3.7 to 7.5 mg per kg bodyweight. Precautions: pregnancy; lactation; clinical and biological surveillance if recommended duration of treatment exceeded; dosage may be halved for patients with renal failure; avoid alcohol; if 'Flagyl' is to be given to patients receiving oral anticoagulants the dosage of the latter should be recalibrated. Side effects and adverse reactions: occasionally an unpleasant taste, furred tongue, nausea, vomiting (very rarely), gastro-intestinal disturbance. Drowsiness, dizziness, headache, ataxia, skin rashes, pruritus, incoordination of movement, darkening of the urine very rarely. During intensive and/or prolonged therapy peripheral neuropathy has been reported. A moderate leucopenia has been reported but the white cell count has always returned to normal before or after treatment has been completed. Transient epileptiform seizures in a few patients undergoing intensive, high-dosage metronidazole radiosensitization therapy.

and E rosette counts in the treated and untreated groups was marginal and further studies need to be made to clarify this.

Leucocyte migration inhibition to tumour extract was demonstrated before surgery by 4 control patients and 3 levamisole patients. Not all patients with colorectal cancer demonstrate migration inhibition to tumour extract (Bull, 1973; Guillou and Giles, 1973). This apparent lack of recognition of tumour antigen has been correlated with extensive disease by Bull (1973), but this was not our experience. Levamisole accelerated the return of preoperative leucocyte migration inhibition following surgery in patients with both local and extensive cancer and abolished the difference between the return of migration inhibition to PPD and that to tumour extract.

The return to preoperative status of PHA-induced blastogenesis was unaffected by levamisole administration. Although at variance with some evidence (Renoux et al., 1977), this observation confirms the studies of Cappel et al. (1975) in the immunosuppressed experimental animal.

The observation that PHA-induced transformation in contrast to leucocyte migration inhibition is unaffected by levamisole is of interest. Leucocyte inhibition measures the production of lymphokines, which are known to be formed in response to a specific antigen. In addition, lymphokines are considered to mediate between stimulated lymphocytes and non-immune macrophages (Fidler, 1975). This has been shown to result in tumour cell destruction *in vitro* (Piessens et al., 1975). As a result, we believe that the leucocyte migration inhibition test is a more specific reflection of the immune status of the cancer patient. In contrast, blastogenesis is a non-specific and perhaps less important expression of the immune response. The ability to produce lymphokines in response to an antigen, against a background of a general depression in cell mediated immunity, is of great interest and may have particular relevance to prognosis following surgery in cancer patients.

Cimetidine in the treatment of peptic ulceration following renal transplantation

G. WILLIAMS AND J. E. CASTRO*

SUMMARY

Seven patients who developed peptic ulceration following renal transplantation have been treated by cimetidine. One died before its value could be assessed. The remaining 6 were symptom-free within 48 h. In 3 patients the ulcer appeared healed on gastroscopy, in one there was no change, another required operation for gastrointestinal bleeding 1 month after beginning cimetidine and the other patient has been lost to follow-up after 5 months' treatment. Two patients had a significant rise of serum creatinine whilst on the drug, but there is no evidence of increased immunological reactivity towards the graft and no agranulocytosis.

THERE is a high incidence of peptic ulceration and related complications in patients on chronic haemodialysis or those who have received renal allografts. Peptic ulcer disease occurred in 48 per cent of patients on regular haemodialysis, and of these 15 per cent bled after transplantation (Doherty et al., 1977). Patients may develop severe dyspepsia or gastrointestinal perforation. Such complications have a high mortality, for of 144 transplants, 14 had upper gastrointestinal bleeding and, despite surgery, all died (Moore and Hume, 1969). Fifteen per cent of our own patients, without dyspepsia during dialysis, developed symptoms within 3 months of transplantation; of these, 6 had gastrointestinal bleeding and 4 of them died (Chisholm et al., 1977).

Cimetidine, a histamine H_2-receptor antagonist, is of increasing interest in the treatment of peptic ulcer (Domschke et al., 1977; Gillespie et al., 1977). Rapid symptomatic relief with healing of the ulcer and avoidance of operation has considerable advantages, especially in uraemic or immunosuppressed patients. However, there is doubt concerning the use of cimetidine in patients with renal transplants. Significant increases in mean plasma creatinine have been reported after administration of the drug (Blackwood et al., 1976; Haggie et al., 1976), and this could be confused with graft rejection, though Jones et al. (1978) showed no alteration in biochemistry in their patients. Furthermore, agranulocytosis after cimetidine has been described (Craven and Whittington, 1977), and combination with azathioprine may result in severe bone-marrow toxicity causing azathioprine to be stopped. In mice, H_2-receptor antagonists inhibit histamine-mediated T lymphocyte cytolysis (Plaut et al., 1973). Cimetidine also prevents histamine-mediated migration inhibition of immune guinea-pig peritoneal exudate cells (Rocklin, 1975). A limited study in humans showed that cimetidine had no effect on mean lymphocyte migration inhibition by BCG and antibody production, but it did cause lower serum concentrations of IgA and IgM in some patients, and increased response to BCG in others (McGregor et al., 1977). No immunological abnormalities were detected during 2 years (De Pauw et al., 1977) of cimetidine treatment of patients with Zollinger–Ellison syndrome.

The high morbidity and mortality associated with peptic ulcer disease in patients after renal transplantation caused us to study the effects of cimetidine in 7 transplanted patients with proved ulcers.

Case reports

Case 1: A 24-year-old male with Still's disease had received prednisone for 11 years. After a haematemesis in 1967 a barium meal showed a duodenal ulcer. X-ray in 1975 was normal, but further radiology after a haematemesis in May 1976 again demonstrated the ulcer. In September 1976 he received a live donor transplant from his father for terminal renal failure due to amyloidosis. Three weeks postoperatively the serum creatinine was 120 μg/l. One month later abdominal pain necessitated gastroscopy which showed hypertrophic rugae and an active chronic duodenal ulcer. There was normal basal acid levels with a raised output after pentagastrin stimulation. Cimetidine 200 mg t.d.s. and 400 mg *nocte* was begun. After 24 h the patient was symptom-free but repeat gastroscopy 5 months later showed no healing. At this time basal and pentagastrin-stimulated acid output were within the normal range. The patient has now received cimetidine at the above dosage for 10 months. There has been no evidence of allograft rejection, serum creatinine has not changed and the white cell count is normal.

Case 2: A male aged 25 years with end-stage renal failure due to hypertension received a live donor allograft from his monther in November 1976. Two rejection episodes were treated with 4 g of methyl prednisolone i.v. One month postoperatively the serum creatinine level was 150 μg/l. Four weeks later the patient had epigastric pain for 3 days and gastroscopy showed two active acute duodenal ulcers. Acid studies were not performed. Cimetidine 200 mg t.d.s. and 400 mg *nocte* was commenced with rapid symptomatic improvement. Gastroscopy after 3 months showed no evidence of duodenal ulcer and the basal acid level was normal, although pentagastrin-stimulated output was slightly elevated. Cimetidine was gradually reduced and stopped over 2 weeks and the patient remained symptom-free. There were no further rejection episodes during cimetidine treatment but serum creatinine rose from 150 to 170 μg 3 weeks after beginning the drug. Values returned to 150 μg/l 1 week after treatment was stopped and the white cell count was unchanged during this period.

Case 3: A 57-year-old male with end-stage renal failure due to hypertension underwent cadaver renal transplant in December 1976. In the first postoperative month he had one rejection episode. Three months later he had upper abdominal pain but gastroscopy was normal. Four weeks later melaena necessitated further gastroscopy, which then showed an active duodenal ulcer. Cimetidine was begun but 4 h later heavy gastrointestinal bleeding necessitated emergency vagotomy and antrectomy. The patient died postoperatively from myocardial infarction.

Case 4: A 30-year-old male with chronic renal failure secondary to chronic glomerulonephritis underwent a cadaver renal transplant in February 1977. Postoperatively he had repeated rejection episodes treated with high doses of steroid. One month later he had upper abdominal pain, but gastroscopy was normal, although barium meal showed a large gastric ulcer. Cimetidine 200 mg t.d.s. and 400 mg *nocte* and carbenoxalone 100 mg t.d.s. was commenced with good symptomatic relief. In April 1977 the patient had massive haematemesis and melaena but at operation there was no gastric ulcer but a large bleeding duodenal ulcer. This was treated by vagotomy and antrectomy with under-running of the ulcer and the postoperative progress was unremarkable. Subsequently, a non-functioning rejected allograft was removed. While on treatment with cimetidine renal function continued to deteriorate slowly with an increase in serum creatinine and a fall in glomerular filtration rate. There was no alteration in the white cell count.

---

* Urology and Transplantation Unit, Hammersmith Hospital, Royal Postgraduate Medical School, Du Cane Road, London.

Case 5: A 37-year-old male underwent a second renal transplant in October 1969. Eight years later epigastric pain for 2 weeks necessitated gastroscopy, which showed a small active duodenal ulcer. Gastric acid studies were not performed. Cimetidine 200 mg t.d.s. and 400 mg *nocte* was commenced with complete symptomatic relief within 48 h. Repeat gastroscopy 2 months later showed a healed duodenal ulcer and cimetidine was slowly reduced and stopped over 4 weeks. Serum creatinine rose from 130 µmol/l to 150 µmol/l during treatment, but fell to 115 µmol/l 1 week after stopping the drug. There was no evidence of allograft rejection and no alteration in the white cell count.

Case 6: A 61-year-old male with chronic renal failure due to chronic glomerulonephritis had a live donor transplant in 1974. After many rejection episodes, serum creatinine stabilized at 300 µmol/l. In 1977 the patient complained of upper abdominal pain and both barium meal and gastroscopy confirmed an active duodenal ulcer. Cimetidine 200 mg t.d.s. and 400 mg *nocte* was commenced and symptomatic improvement was excellent. After 2 months the cimetidine dose was halved. The patient subsequently returned to his own country and no further clinical details are available. During the first 2 months of cimetidine there was no deterioration of renal function or alteration of the white cell count.

Case 7: A 41-year-old female with chronic renal failure due to chronic glomerulonephritis underwent a live donor transplant in 1971. In 1977 she developed upper abdominal pain and gastroscopy showed a duodenal ulcer. Cimetidine 200 mg t.d.s. and 400 mg *nocte* gave good symptomatic relief. Repeat gastroscopy showed healing of the ulcer and cimetidine was stopped. There was no recurrence of symptoms during treatment and there was no alteration in the creatinine level or the white cell count.

All 7 patients were taking prednisolone and azathioprine during cimetidine therapy. Some were taking antihypertensives as necessary.

Discussion

These preliminary studies show cimetidine to be of some value in the management of patients who develop peptic ulceration following renal transplantation. The previously reported immunological effects of H_2-receptor antagonists did not appear to provoke allograft rejection. Of the 7 patients in this series, 3 showed a rise in serum creatinine whilst on treatment. In 1 patient (*Case* 4), this could be explained by chronic allograft rejection, but in the other 2 (*Cases* 2 and 5) this was probably attributable to cimetidine, for serum creatinine fell to pre-treatment levels soon after the drug was stopped. The rise of the creatinine level was slow and only just reached significant levels. There were no other features to suggest graft rejection, and although this has to be considered, we have found no difficulty in distinguishing this rise from that which would occur during a rejection episode. Agranulocytosis has not been seen in any of our patients, despite concomitant therapy with azathioprine.

The healing of peptic ulcers following therapy with cimetidine was encouraging. Apart from 1 patient (*Case* 3) who died within 16 h of beginning treatment, all the patients had rapid symptomatic relief. In 3 patients the ulcers healed. In one the gastroscopic appearances remain the same after 5 months whilst another had surgery for severe intestinal bleeding 1 month after commencing cimetidine. The remaining patient has remained abroad but he was known to be symptom-free 5 months after commencing treatment.

From the results of these preliminary studies it appears to be safe to give cimetidine to patients who develop peptic ulceration after transplantation; rapid healing of the ulcer can be expected in some patients. Further studies are necessary to determine the efficiency of the treatment and whether prophylactic therapy is valuable for lowering the high incidence of ulceration in such patients.

Does rectal examination affect serum acid phosphatase levels?

S. K. BANNERJEE, I. F. BARKER AND T. A. WATERWORTH*

SUMMARY

Formol-stable serum acid phosphatase (SAP) was measured in 200 patients with symptoms of prostatism, before and at varying time intervals after digital rectal examination. In three separate groups of 50 patients SAP levels were measured before and at 5, 15 and 30 min following rectal examination and in a fourth group of 50 patients it was measured before and at 6, 24 and 48 h after examination. No significant change occurred in SAP levels following this examination in any of the groups studied. We conclude that rectal examination does not raise the SAP and that, contrary to popular belief, blood levels recorded at any time within this 48-h period are reliable.

It has been generally accepted that serum acid phosphatase (SAP) levels measured within 48 h following digital rectal examination may be raised and that the test is therefore unreliable during this period (Woodward, 1959; Longley, 1965; Rains and Ritchie, 1969; Bodansky, 1972; Wilkinson, 1976). The purpose of the present study was to investigate whether the SAP levels altered at different time intervals following this examination. The modified King–Armstrong method used has been well established as a reliable method for measuring prostatic acid phosphatase.

Patients and methods

A total of 200 male patients over the age of 50 years with varying surgical and medical conditions and all with the symptoms of prostatism was subjected to digital rectal examination in the left lateral position by three different surgeons. To standardize the rectal examination as far as possible the following method, as described in *Demonstrations of Physical Signs in Clinical Surgery* by Hamilton Bailey (Clain, 1967), was used and the findings were carefully recorded:

1. Anteriorly—prostate, seminal vesicle, rectovesical pouch. Prostate—size (lobe), consistency, mobility, mucosa, sulcus, induration etc.
2. Left and right lateral rectal wall.
3. Posteriorly—hollow of sacrum and coccyx.

Blood samples were taken before and at intervals of 5, 15 and 30 min following rectal examination in each of the three groups of 50 patients and in a fourth group of 50 patients at intervals of 6, 24 and 48 h.

The SAP levels were determined by a modified King–Armstrong method which is based upon the hydrolysis of p-nitrophenyl phosphate with the liberation of phenol, the phenol so formed being estimated colorimetrically (Dhmori 1937; King and Delory, 1939; Jacobson, 1960). The result, in King–Armstrong units, is expressed as milligrammes of phenol liberated per 100 ml of serum in 15 min at 37 °C, each unit corresponding to the liberation of 1 ml of phenol per 100 ml of serum. Acid phosphatase is very unstable and so the serum was separated immediately and stored at −20 °C. The tests were carried out in small batches.

Erythrocytes contain appreciable acid phosphatase activity and, even in the absence of haemolysis, red cell enzyme may be released into the serum. The addition to the reaction mixture of 0·5 per cent formaldehyde completely inactivates red cell acid phosphatase without inhibiting the prostatic fraction (Abdul Fadl and King, 1948, 1949). The determination is based upon the principle that, in the absence of alkaline oxidizing agents, 4-amino antipyrine gives a red colour with phenolic compounds (Kind and King, 1954, Powell and Smith, 1954).

Table I: SAP LEVELS BEFORE AND AFTER DIGITAL RECTAL EXAMINATION

		Mean	s.d.	t	P value
At 5 min 47 patients (3 excluded; Ca. prostate)	Pre-RE Post-RE	1·75 1·80	±1·64 ±1·63	−0·176	>0·6
At 15 min 49 patients (1 excluded, Ca. prostate)	Pre-RE Post-RE	1·46 1·35	±0·91 ±0·68	0 670	>0·5
At 30 min 48 patients (2 excluded, Ca. prostate)	Pre-RE Post-RE	1·50 1·45	±0·79 ±0·86	0·306	>0·7

Ca., Carcinoma; RE, rectal examination.

Table II: SAP LEVELS BEFORE AND AFTER DIGITAL RECTAL EXAMINATION

		Mean	s.d.	t	P value
At 6 h	Pre-RE Post-RE	1·426 1·359	0·691 0·457	0·556	<0·6>0·5
At 24 h	Pre-RE Post-RE	1·426 1·553	0·691 0·660	0·933	>0·4
At 48 h	Pre-RE Post-RE	1·426 1·304	0 691 0·560	1·0204	>0·3

RE, Rectal examination.

The serum was incubated with citrate buffer, pH 4·9, and p-nitrophenyl phosphate as substrate for 1 h at 37 °C. The reaction was stopped by the addition of 0·5 M sodium hydroxide, 0·5 M sodium bicarbonate, 0·6 per cent 4-amino antipyrine and 2·4 per cent potassium ferricyanide and the extinction measured at 510 nm. The standard was prepared from pure crystalline phenol in HCl. The reference range is 0·5–3·5 KA units/dl (mean ±2 s.d.).

Results

The SAP levels before and following the rectal examination in three different groups of 47, 49 and 48 patients at respective time intervals of 5, 15 and 30 min were analysed by the unpaired Student's t test. In none of these groups was there any significant change in SAP levels following rectal examination (P value >0·6, >0·5, >0·7, *Table I*). In the fourth group of 50 patients the SAP levels at 6, 24 and 48 h were also analysed by the unpaired t test and no significant change between pre- and post-rectal examination SAP levels was demonstrated (P values >0·5, >0·4, >0·3, *Table II*).

It was thought that age might influence SAP levels following rectal examination and therefore the patients were divided into three age groups: 50–59 years (45 patients), 60–69 years (78 patients) and 70 years and over (71 patients). In none of these groups was there any significant change in pre- and post-rectal examination SAP level when analysed by the unpaired t test (P values >0·3, >0·4, >0·9, *Table III*).

Table V: SAP LEVELS IN 6 PATIENTS WITH CARCINOMA OF THE PROSTATE

Patient	Pre-RE	Post-RE	SAP
1	12·5	11·8	↓
2	5·79	2·37	↓
3	3·0	2·50	↓
4	2·0	4·25	↑ (+2 s.d.)
5	1·5	3·0	↑ (+2 s.d.)
6	2·0	2·0	=

It has been suggested that local complications such as urinary tract infections, recent catheterization or obvious bladder pathology may influence SAP levels. To exclude this possibility the patients were divided in two groups, those with simple hypertrophy alone (149 patients) and those with the above-mentioned complications (45 patients). In neither of these groups was there any significant change in the SAP levels (*P* value >0·7, >0·6, *Table IV*).

In this series 11 out of 194 patients (5·6 per cent) had SAP values below the lower limit of normal before rectal examination. In 3 of these patients the SAP was raised following rectal examination to within normal limits (0·25 to 0·5, 0·25 to 1·0, 0·45 to 0·5). In 1 patient the SAP level fell to below the lower limit of normal (0·75 to 0·25) following examination. In 7 patients it remained unchanged. In this series no patient was found to have a level of 3·5 either before or after examination. Six patients were subsequently found to have histologically proved carcinoma of the prostate and therefore were not included in the following analysis. It is interesting to note that in 6 patients with carcinoma of the prostate there were wider variations in the levels of SAP before and after rectal examination (*Table V*).

Discussion

It has been established that prostatic massage does increase the level of SAP (Woodward, 1959; Wilkinson, 1976), but it appears that a certain amount of confusion has arisen in the past concerning SAP levels following rectal examination or recent catheterization. It has been stated that mild trauma to the prostate, e.g. catheterization or rectal examination, will cause transitory elevation of SAP (Wilkinson, 1976). The instability of SAP may have contributed to previous confusion, not only because it is very labile on storage, but also one previous trial used heparinized blood, and it has been shown that heparin interferes with the analysis of the prostate fraction (Dybkaer and Jenson 1958; Woodward, 1959). Our findings clear the confusion. This is important in outpatient departments where a rectal examination has been done and there is clinical suspicion of prostatic pathology; the SAP level still can be measured reliably on the same sample of blood taken for other biochemical investigations. The patient does not have to wait for 48 h before a second blood sample is taken. It saves time for both surgeon and patient. When a patient presents with acute retention of urine he can safely be catheterized before blood is taken and the SAP level can be relied upon. Raised SAP levels should not be ignored because blood was taken for the estimation within 48 h of a rectal examination.

Sparks mandril, velour Dacron and autogenous saphenous vein grafts in femoropopliteal bypass

J. T. CHRISTENSON AND B. EKLÖF*

SUMMARY

Ninety-nine consecutive vascular reconstructions with femoropopliteal bypass performed during 1973–6 have been reviewed. A Sparks mandril was used in 11 patients, reversed autogenous saphenous vein in 30 and velour Dacron prostheses in 58. The indication for operation was severe ischaemia in 79 per cent. The overall patency rate at 12 months was 70 per cent for autogenous vein, 46 per cent for velour Dacron prosthesis and 18 per cent for Sparks mandril. When the distal anastomosis was located above the knee the patency rate was 100 per cent and 87 per cent for autogenous vein and velour Dacron graft respectively, while the corresponding figures for distal anastomosis below the knee were 58 per cent and 11 per cent. At follow-up 60 per cent of the patients showed improvement owing to the vascular reconstruction.

MANY methods of revascularization of the lower limb in ischaemia have been recommended. In those techniques in which no 'foreign' material is used, such as thrombendarterectomy (Wylie et al., 1964) or thrombendarterectomy with patch graft, a 5-year patency rate of 42–60 per cent is described (Vollmar et al., 1968). Results at almost the same level are obtained when profundaplasty is used as an alternative method of limb salvage (Martin and Bouhoutsos, 1977). The same results are claimed after extended profundaplasty where a limb salvage rate of approximately 50 per cent has been reported (Martin et al., 1972; Berguer et al., 1973; Cotton and Roberts, 1975). It is quite clear, however, that the majority of authors regard the femoropopliteal bypass procedure as the method of choice for the treatment of obliterative disease of the leg.

Femoropopliteal bypass using autogenous venous transplants was first descibed by Kunlin in 1949. Since then a great many reports have described excellent results with this technique (Szilagyi et al., 1964; Crawford et al., 1966; Darling et al., 1967; DeWeese and Rob, 1977), some of these reports showing a 2-year patency rate of 70–90 per cent and a 10-year patency rate of 40–60 per cent.

As recently as 1975, it was stated by Crawford that: 'As far as the graft is concerned, there is nothing better than a good autogenous saphenous vein graft. Conversely, there is nothing worse than an inadequate autogenous saphenous vein.' A good venous substitute is not always available. The smallest part of the vein to be used should have a minimum of 5 mm external diameter when distended. It should not be diseased and must not be damaged during removal (Barker et al., 1976). Frequently therefore, another arterial substitute has to be found.

In the search for substitutes, synthetic material such as Teflon and Dacron has been tried widely. Dacron grafts in femoropopliteal vascular reconstructions have led to excellent results in the early postoperative phase with a patency rate at the level of 30–60 per cent after 1–5 years (Vollmar et al., 1968; DeBakey et al., 1973). Slightly better results have been recorded when knitted velour Dacron prostheses have been used, with a patency rate of 70 per cent after 5 years often described (DeBakey et al., 1973). A completely different technique involves the use of collagen tubes —Sparks mandril (Sparks, 1973). However, up to now the results have not been acceptable, with a patency rate after 2 years of 26 per cent (Hallin and Sweetman, 1976).

This present study compares the results of femoropopliteal reconstructive surgery utilizing Sparks mandril, velour Dacron and autogenous saphenous vein grafts. Special emphasis is placed on factors relating to graft failure and other complications of importance in limb salvage.

Patients and methods

Patients

From January 1973 to December 1976 99 consecutive femoropopliteal bypass reconstructions were carried out in 21 women and 78 men with arteriosclerotic obliterative disease of the lower limb. The average age was 62 years (range 25–87 years). The autogenous saphenous vein was used if the vein was available and after excision could be distended to at least 5 mm in diameter. When a suitable vein was not available a velour Dacron graft or Sparks mandril was used. The number of patients in each group is shown in *Table I*. Seventy-three patients had a severe ischaemia of the lower extremity (including rest pain, with or without gangrene), while 26 patients had a disabling intermittent claudication. The average duration of symptoms before operation was 25 months (range 1–122 months). The follow-up was from 1 year up to 5 years.

Table I: TYPE OF ARTERIAL SUBSTITUTE IN PATIENTS WITH SYMPTOMS OF SEVERE ISCHAEMIA AND INTERMITTENT CLAUDICATION

Arterial substitute	No. patients with severe ischaemia	No. patients with claudication	Total
Velour Dacron	46	12	58
Autogenous saphenous vein	20	10	30
Sparks mandril	7	4	11
Total	73	26	99

Run-off classification

The run-off was classified according to the run-off index described by Morton et al. (1967). Points are awarded to the distal popliteal artery and each of its branches, as seen on angiograms in two different projections. Each patent artery scores 4 points, 25 per cent stenosis 3 points, 50 per cent stenosis 2 points, 75 per cent stenosis 1 point and a total occlusion of the artery, zero. A normal angiogram of the calf vessels, therefore, yields 16 points. The patients were divided into three groups according to this index: stage I, patients with 16–12 points; stage II, patients with 11–7 points; and stage III, patients with 6–0 points.

Clinical physiology

Distal pressure measurement of the big toe was performed in all the patients using the strain-gauge technique (Gundersen, 1972) preoperatively and approximately 1 month postoperatively.

---

* Department of Surgery, University of Lund, Sweden.

Velour Dacron graft

Fifty-eight patients were treated with a DeBakey Vasculour-D knitted velour Dacron arterial graft 6 mm in diameter. Twenty-two patients had had previous vascular reconstructions in the lower leg. Twenty-eight patients had gangrene of the foot or toes Seventy-one per cent of the patients were heavy smokers. At operation an end-to-side anastomosis was performed to the common femoral artery above the bifurcation and distally an end-to-side anastomosis to the popliteal artery, in 39 cases above the knee and in 19 cases below the knee. All grafts were pre-clotted.

Sparks mandril

Sparks mandrils were used in 11 cases. The silicone mandril consists of a smooth silicone rubber rod (outside diameter 6 mm) covered with two layers of large mesh, knitted Dacron tubes. It is implanted subcutaneously in the thigh, through the popliteal fossa to the calf (Sparks, 1973). After at least 6 weeks, during which time an autogenous tube grows around the mandril, encapsulating the Dacron tube, the silicone rod is withdrawn and the new Dacron-reinforced autogenous graft is anastomosed end-to-side to the common femoral artery and the distal popliteal artery below the knee in all cases. Three patients had had previous vascular reconstructions. Three patients had gangrene of the toe or foot: 73 per cent were heavy smokers.

Autogenous saphenous vein grafts

Thirty patients had a reversed autogenous saphenous vein graft with the distal anastomosis below the knee in 12 cases and above the knee in 18. The proximal anastomosis was in all cases made in the common femoral artery. Four patients had had earlier vascular reconstructions. Eight patients had gangrene in the foot or toe: 67 per cent of the patients were heavy smokers.

Results

Postoperative complications

Early graft thrombosis within 1 month was seen in 29 per cent of the cases while late thrombosis occurred in 25 per cent of the series. Postoperative wound infections were seen in 17 per cent. However, most of these infections were noted during 1973–4. Since we instituted better hygienic routines and prophylactic antibiotics in 1975 there has been very little infection (Christenson et al., 1979). Postoperative pulmonary insufficiency was recorded in 5 patients, as was myocardial infarction. Postoperative haemorrhage was noticed in 4 patients of whom 3 were re-explored. As regards the differences between the three types of graft, there was early graft thrombosis in 7 of the Sparks mandril cases, in 18 of 58, velour Dacron grafts and in 4 of 30 autogenous vein reconstructions. Successful thrombectomy with good long term results was performed in 13 of the 18 patients with a velour Dacron prosthesis. The same was true for 1 of the 4 patients in the autogenous vein group and for the only patient requiring thrombectomy in the Sparks mandril group (*Table II*). Thrombectomy in late graft thrombosis (12 velour Dacron grafts) was unsuccessful in all cases.

Mortality

The hospital mortality within 1 month of operation was 4 per cent (3 patients in the velour Dacron group and 1 patient in the autogenous saphenous vein group). The cause of death was myocardial infarction. There was no mortality in the group where the indication for operation was intermittent claudication. The late mortality was 6 per cent; in 1 case this was due to a pancreatic cancer, but in the remaining patients it was because of myocardial infarction.

Follow-up study

All patients have been followed up for at least 12 months. The patency rate after 12 months was 70 per cent for autogenous saphenous vein graft, 46 per cent for velour Dacron prosthesis and 18 per cent for Sparks mandril. Several of the grafts are functioning after a longer time. One Sparks mandril has been patent for 38 months. This graft was implanted subcutaneously for 6 months before it was used for reconstruction.

The early patency rate in relation to the location of distal anastomosis was good when this anastomosis was above the knee, with 100 per cent patency for the autogenous vein graft and 87 per cent patency for the velour Dacron graft. There were no significant differences between the two types of graft. When the distal anastomosis was below the knee the autogenous

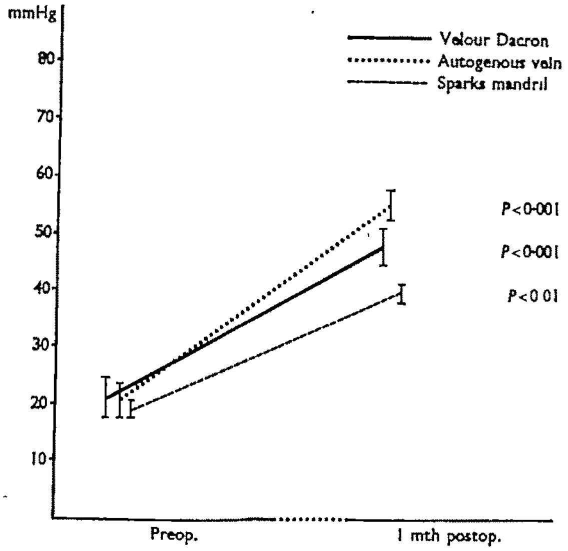

Fig. 1. Pre- and postoperative distal blood pressure in the big toe of the reconstructed leg (mean ± s.e. mean).

vein graft had a patency rate of 58 per cent, which was significantly higher ($P < 0{\cdot}01$) than that of 11 per cent for velour Dacron grafts.

Further reconstructions were performed after failure of the primary operation. In the autogenous vein graft group 1 patient had an axillofemoral bypass and 1 patient had a new femoropopliteal bypass. In the velour Dacron group 2 patients had iliofemoral bypass, 1 patient an axillofemoral bypass and 2 patients another femoropopliteal bypass. Two patients in the Sparks mandril group were further reconstructed with a femoropopliteal bypass.

The amputation rate was 38 per cent in patients with severe ischaemia and one patient with intermittent claudication had an amputation. This patient had a bad run-off (stage II) combined with advanced diabetes mellitus and the indication for operation was dubious. If the run-off was classified as stage I or II there were no differences in the amputation rate, showing 21 per cent and 24 per cent respectively, while it was doubled (46 per cent) in cases with stage III run-off ($P < 0{\cdot}02$). A bad run-off index (stage III) in the velour Dacron group resulted in the highest amputation rate—53 per cent (*Table III*).

The effect of the location of the distal anastomosis on the amputation rate is shown in *Table IV*. Five of 12 patients with the autogenous vein graft below the knee had amputations and 17 of 19 patients in the group with the velour Dacron prosthesis below the knee. When the distal anastomosis was above the knee in patients with autogenous vein grafts there were no amputations, while there were 5 amputations in 39 patients with velour Dacron grafts, all in stage II and III patients.

Distal blood pressure in the big toe was investigated in all patients before operation and again in patients who had not had amputations about 1 month after reconstruction (*Fig.* 1). A statistically significant increase in pressure was noted.

At follow-up the patients were classified as improved if their symptoms had disappeared, tissue lesions had healed and they had been able to resume their normal activity. Sixty patients had improved while 39 were unchanged or worse, resulting in amputation in 29 of these patients. All amputations were below the knee and in at least 13 patients the vascular reconstruction contributed to lowering the level of amputation. Of the amputees, 76 per cent tolerated their leg prosthesis and were well rehabilitated.

Discussion

Patients with distal arteriosclerotic disease with symptoms of severe ischaemia can be managed in several ways, e.g. with femoropopliteal bypass procedures in order to improve their symptoms, save the limb or at least lower the level of a demanded amputation. The use of autogenous vein grafts is well documented as either a reversed or an *in situ* bypass (Skagseth and Hall, 1973). We have also had good results using the reversed great saphenous vein, with a patency rate of 70 per cent after 12 months. If the distal anastomosis is placed above the knee, patency is 100 per cent, while reconstructions below the knee reduce the patency rate to 58 per cent.

When a suitable autogenous vein is not available, different synthetic materials have been used. It has been reported (Crawford, 1975) that 8-mm knitted Dacron grafts with the distal anastomosis below the knee give the same patency rate as that achieved with the reversed autogenous vein. Our findings do not corroborate these results. Velour Dacron grafts with the distal anastomosis above the knee gave a patency rate after 12 months of 87 per cent, which is good, while the patency rate was reduced to an unacceptable 11 per cent if the distal anastomosis was below the knee. The distal run-off was worse in patients receiving velour Dacron grafts, with 70 per cent of patients classified as stage II–III compared with 58 per cent of patients with autogenous vein grafts.

The enthusiastic report on the use of Sparks mandril (Sparks, 1973) has not been verified in our study. We achieved a patency rate after 12 months of only 18 per cent. It is interesting to note, however, that one Sparks mandril has been patent for more than 3 years. This mandril was introduced subcutaneously for 6 months before it was used for reconstruction.

The search for new and better synthetic vascular grafts for below-knee reconstructions in the absence of an adequate autogenous vein is important. The Gore-Tex graft (expanded polytetrafluoroethylene) has in several preliminary reports shown a good patency in below-knee reconstructions: 89 per cent patency after 3 months (Veith et al., 1977), cumulative patency rate within 18 months of 59 per cent (Haimov et al., 1977), and 85 per cent within 20 months (Raithel and Groitl, 1977).

The umbilical cord vein chemically treated in different ways (with alcohol, formalin or glutaraldehyde) has been reported to have good properties for use below the knee and a cumulative patency rate of 70 per cent after 16 months has been reported (Dardik et al., 1976). However, it is equally important to develop preoperative methods to evaluate the run-off of the distal leg and foot in order to choose the right patients for this limb salvage operation.

Reduction in road fatalities and injuries after legislation for compulsory wearing of seat belts: experience in Victoria and the rest of Australia

F. T. McDERMOTT AND D. E. HOUGH*

SUMMARY

In 1970 the Government of the State of Victoria became the first in the 'western' world to introduce legislation for compulsory wearing of seat belts. Within 14 months the other Australian states followed. Seat belt wearing rates increased to attain 90 per cent in 1977.

This paper presents an evaluation of changes during the period 1955–77 in the incidence of road crash fatalities and injuries for vehicle occupants in Victoria and the rest of Australia.

The introduction of the legislation in Victoria and subsequently in the other Australian states coincided with significant and marked decreases in driver and passenger fatality and injury rates (numbers per 10 000 registered vehicles). The decreases were enough to reduce the total numbers of vehicle occupant fatalities and injuries for all post-legislation years in Victoria. The improvements have been maintained throughout the entire post-legislation period.

The legislation did not apply to child passengers of less than 8 years of age and the frequency of seat belt or harness wearing among them remained low. These children did not share in the overall improvement for passengers.

The Australian experience supports the view that legislation for compulsory wearing of seat belts is the single most effective method available for the protection of vehicle occupants in road crashes.

A CAMPAIGN for compulsory wearing of seat belts initiated by the Road Trauma Committee of the Royal Australasian College of Surgeons and the Melbourne media led to the Government of Victoria's becoming, on Friday, 22 December 1970, the first in the 'western' world to introduce legislation for this purpose (McDermott, 1978). Children under the age of 8 were excluded. The Government of New South Wales acted similarly in October 1971 and all other Australian states had followed by the end of January 1972. Additional legislation requiring that seat belts be fitted to older model motor vehicles was later introduced in all states. The percentage of Melbourne metropolitan drivers wearing seat belts increased from 15 per cent in the year before legislation to 65 per cent in 1973 and 90 per cent in 1977 (Vulcan, 1977; Road Safety and Traffic Authority of Victoria, 1978). The percentage for passengers was 4 per cent lower. In country areas the wearing rates have been approximately 10 per cent lower for both drivers and passengers. Comparable changes have occurred throughout Australia (Vaughan et al., 1974; McKenzie and Milne, 1976; Vaughan, 1977).

The hypothesis that seat belt wearing mitigates injury and improves survival prognosis for vehicle occupants involved in road crashes has been supported by previous Australian studies (Crinion et al., 1975; Trinca and Dooley, 1975; McDermott, 1978). Comprehensive road crash and injury data were obtained during 1971–3 in Victoria by the Royal Australasian College of Surgeons on 36 077 vehicle occupant casualties (Nelson, 1974). Analysis showed that casualties wearing seat belts had a lower probability of ejection, received fewer major or fatal injuries to the head and neck, trunk and upper extremities and had a lower probability of death (Nelson, 1974, 1977; Cameron and Nelson, 1977). The incidence of concussion, primary severe brain damage, intracranial compression and skull and facial fractures was significantly decreased in vehicle occupant casualties wearing seat belts (Cameron and Nelson, 1977). Cervical whiplash was the only injury with a significantly increased frequency in those wearing seat belts. The protection afforded by a seat belt appeared to be greater in frontal than in side impacts (Trinca and Dooley, 1975). Other studies have indicated a reduction in the incidence and severity of both spinal cord (Burke, 1977) and head injuries (Petty, 1975, 1977).

The protective value of seat belts is also supported by international experience. The enactment of legislation for compulsory wearing of seat belts has everywhere been followed by decreases in the incidence of vehicle occupant fatalities and injuries: in New Zealand the reduction was approximately 15 per cent (Toomath, 1977); in Sweden the number of road crash casualties admitted to 16 major hospitals was reduced by 29 per cent (Andreasson and Roos, 1977); and in France the occurrence of fatal injuries for front seat casualties was found to be approximately 65 per cent less than that found in those not wearing seat belts (Chodkiewicz and Dubarry, 1977). In Belgium compulsory seat belt wearing legislation was followed in the first 4 months by a 37 per cent reduction of fatalities and injuries (*British Medical Journal*, 1977). An analysis of 9000 front seat casualties in the United States, where seat belt wearing is not compulsory, showed that the incidence of severe or fatal injuries was reduced by about 65 per cent in those wearing seat belts (Huelke et al., 1977).

This paper examines changes in the incidence of road crash fatality and injury among vehicle occupants in Victoria and the rest of Australia for the period 1955–77. An evaluation is made of the significance of any altered trends after the introduction of legislation for compulsory wearing of seat belts.

Methods

Data

The annual numbers of road accident fatalities and injuries between 1955 and 1977 were obtained from the Australian Bureau of Statistics for motor vehicle occupants. For child passengers less than 8 years of age data were not available for 1955–6. Fatality and injury rates per 10 000 registered vehicles (motorcycles not included) were calculated for Victoria and for the rest of Australia (i.e. Australia minus Victoria).

Statistical analysis

The significance of changes in the annual numbers of fatalities and injuries and in fatality and injury rates per 10 000 registered vehicles following the introduction of compulsory seat belt wearing have been evaluated by linear regression analysis and the non-parametric Mann–Whitney U test (Siegel, 1956).

Linear regression analysis: Pre-legislation data were subjected to linear regression analysis. The 95 per cent confidence limits were calculated and extrapolated for prediction of the range of expected post-legislation values.

Mann–Whitney U test: Differences in fatality and injury parameters between the sums of consecutive pairs of years were calculated. The differences of the first 4 post-legislation years (Victoria, 1971–4; rest of Australia, 1972–5) were compared with those before and after this period. Post-legislation differences which did not attain the 5 per cent level were considered non-significant.

Results

Driver fatalities and injuries

The results are summarized in *Table I.* Fatality and injury numbers and rates were less than predicted for each post-legislation year in Victoria. Post-legislation differences were reduced. Fatality and injury rates were also decreased for the rest of Australia. *Fig.* 1 shows the reduction in the fatality rates for Victoria and for the rest of Australia.

Passenger fatalities and injuries

The results are summarized in *Table II.* The numbers of passenger fatalities and injuries were decreased in Victoria. Fatality rates were decreased for Victoria for each post-legislation year but for only the last year in the rest of Australia (*Fig.* 2). Injury rates were decreased for all post-legislation years.

Child passenger fatalities and injuries

The results for children under the age of 8 are summarized in *Table III.* The numbers of fatalities and injuries were within predicted limits except for a decrease in injury numbers for the last 5 post-legislation years in Victoria. Fatality rates remained within the 95 per cent confidence limits (*Fig.* 3). Injury rates were decreased for each post-legislation year in Victoria but only for the last year in the rest of Australia.

Discussion

The introduction of legislation for compulsory wearing of seat belts in Victoria and subsequently in the other Australian states coincided with significant reductions in road fatalities and injuries among vehicle occupants. There have been no comparable changes for motorcyclists or pedestrians (Road Safety and Traffic Authority of Victoria, 1978). Despite increases in the number of registered vehicles, fuel consumption and population (Vulcan, 1977), the improvements have been maintained throughout the entire post-legislation period.

In Victoria and the other Australian states driver fatality and injury rates were shown by linear regression analysis to be significantly decreased. These decreases were enough to reduce the total numbers of driver fatalities and injuries for all post-legislation years in Victoria. Passenger fatality and injury rates were significantly reduced for all post-legislation years in Victoria. Except for the first post-legislation year, the total number of passenger injuries was also decreased for each post-legislation year. While the passenger injury rate for the rest of Australia was reduced, the decrease in fatality rate did not attain significance. The finding that reductions in fatality and injury were relatively less for passengers than for drivers may be related to their lower seat belt wearing rates.

The results of non-parametric statistical evaluation were in general agreement with those shown by linear regression analysis. In addition, significant decreases were demonstrated in the total number of passenger fatalities in Victoria and in the fatality rate and the total number of fatalities of child passengers under the age of 8 in the rest of Australia.

The reduction in vehicle occupant fatalities and injuries in Victoria was greater than in the rest of Australia and may be explained by additional factors operating in that state. These factors possibly include a maximum speed limit of 100 km/h introduced in 1974 and more comprehensive legislative countermeasures to drink–driving behaviour introduced in 1974 and 1976. An alteration in the criterion for police reporting of non-fatal injuries introduced in 1972 in Victoria is believed to account for part of the reduction in that state.

Legislation for compulsory wearing of seat belts had not applied to child passengers of less than 8 years of age. As a consequence the frequency of seat belt or harness wearing for child passengers remained low (Boughton et al., 1977; King, 1977). These children did not share in the overall improvement for passengers. The fatality rate for 0–7-year-olds was not reduced although differences attained significance for the rest of Australia. There has, however, been a reduction in non-fatal injuries, albeit smaller than that for the total passenger group. The injury rate was less than predicted for all post-legislation years in Victoria and for 1977 in the rest of Australia. The total number of injuries was also reduced in Victoria for the last 5 years of the post-legislation period. These improvements may be partly explained by legislation introduced in Victoria in 1975 making seat belt or harness wearing compulsory for children occupying front seats and subsequent legislation in New South Wales and Western Australia applied to all children. There is an urgent need for the further development and evaluation of child restraint systems and for an extension of compulsory seat belt wearing legislation throughout Australia to all child passengers.

Experience in Victoria and the other Australian states supports the hypothesis that seat belt wearing reduces the likelihood of injury to vehicle occupants involved in road crashes and increases the prognosis for survival. Legislation for compulsory wearing of seat belts remains the single most effective measure available for the protection of vehicle occupants in road crashes.

The benefit of legislation for compulsory wearing of seat belts would be increased by greater public compliance. Surveys in Victoria (Nelson, 1974) and Western Australia (Court, 1977) have shown that the frequency of seat belt wearing in vehicle occupants involved in road crashes is less than that of sample populations. Between 1972 and 1975 in Western Australia, police attended 25 948 road crashes involving 67 687 casualties. The seat belt wearing rates among fatal and non-fatal casualties were only 30 per cent and 37 per cent, respectively. Of vehicle occupants not wearing seat belts, 2·3 per cent were killed and 40 per cent injured. On the other hand, only 0·7 per cent of those wearing seat belts sustained fatal injuries and 16 per cent non-fatal injuries.

The results presented support the view that governments that enact legislation making seat belt use compulsory are reducing the risk of fatality and injury for vehicle occupants involved in road crashes.

A study of basal cell carcinoma of the inner canthus, 1967–72

JOHN C. McGREGOR*

SUMMARY

Basal cell carcinoma was the commonest malignant lesion at the inner canthus. Reconstruction following excision was most commonly achieved with a post-auricular full thickness graft. Provided excision is adequate, a local flap is a good alternative. There is no evidence that the use of a graft increased recurrence, but it may have allowed earlier detection. The primary recurrence rate after primary surgical excision was 3·6 per cent. Recurrence occurred in several cases when histology indicated incomplete excision. Follow-up under these circumstances should be continued for up to 10 years. When adequate primary surgical excision was performed, there was no evidence that rodent ulcer of the inner canthus behaves differently or has a worse prognosis than at other sites. There has probably been undue concern in the past about epiphora following resection of the lacrimal drainage system.

RODENT ulcer at the inner canthus has a sinister reputation (Bennett, 1974). However, there have been no reports to suggest the prognosis is any worse than elsewhere. There has also been debate regarding the best method of reconstruction following excision. Hirshowitz and Mahler (1971) have suggested that repair with grafts rather than flaps is more satisfactory in order to allow earlier detection of recurrence. Taylor and Barisoni (1973), on the other hand, suggested that the use of grafts was associated with an increased incidence of recurrence.

For these reasons, it was decided to carry out a retrospective study of lesions of the inner canthus treated at Canniesburn Hospital over the period 1967–72. Forty-one males and 46 female patients with a total of 88 rodent ulcers were recorded. The age range was 24–81 years (maximum incidence 5th and 6th decades). The average diameter was 0·97 cm (range 0 3–2·0 cm). In 7 males and 1 female basal cell carcinomas were or had been present at other sites.

Patients and methods

Management

General anaesthesia was employed in 75 of the rodent ulcers. The remainder were excised under local anaesthesia. The majority of the defects following excision were repaired with post-auricular full thickness grafts and the remainder by a variety of local flaps or direct closure (*Table I*). The glabellar flap was the most commonly used flap. The puncta were involved in 7 patients and an attempt to reconstruct the drainage system, using silicone tubing or nylon sutures, was made in 2 cases.

In all but one case comment was made on the completeness of excision. The limits were definitely involved in 13 and possibly so in 4 cases. Eight were reported as multifocal rodent ulcers.

Recurrence

A recurrence rate of 3·6 per cent (2 females, 1 male) was recorded in those having primary surgery in the series. In all these the defect had been grafted. Pathology revealed incomplete excision at the deep margin in 2 cases and at the lateral margin in one other case. The recurrences presented 2, 4 and 7 years after initial surgery. Two have been clear of further recurrence for 1 and 4 years respectively; the third has so far required four re-excisions.

Table I: METHODS OF REPAIR FOLLOWING EXCISION OF RODENT ULCERS OF THE INNER CANTHUS

	Male	Female	Total
Direct closure	2	4	6
Skin graft			
Split	1	0	1
PAWG	26	23	49
Supraclavicular	2	0	2
Nasolabial	1	0	1
Flap			
Glabellar	4	9	13
Eyelid	2	4	6
Cheek or forehead	3	2	5
Unspecified	1	4	5

There were 8 male and 1 female patients who had primary treatment elsewhere. In 2, the nature of the previous treatment was unrecorded; in 2, surgical excision had been performed 7 and 9 years prior to recurrence. In the remaining 5 patients, the recurrence occurred from 6 months to 5 years after radiotherapy. Following secondary surgery, the limits of excision were reported as clear. No further recurrence has been reported (follow-up 2–4 years).

Complications following surgery

Epiphora was reported in 8 cases, but in 3 it was transient. The repair had been with a graft in 3 cases; in the remainder, a flap had been used. The puncta or nasolacrimal system had been excised in 5 cases with an attempt at reconstruction in 2 cases. In no case was the epiphora described as being severe or incapacitating.

Ectropion was recorded in 6 cases, but in 4 it was transient. Flap repair had been used in 2 cases, grafts were used in the remainder. Ectropion and epiphora occurred together in 3 cases.

Discussion

Basal cell carcinoma was found to be the most common skin lesion requiring excision at the inner canthus. In the majority of cases operation was performed under general anaesthesia and reconstruction in 60·9 per cent was with post-auricular full thickness grafts. There was no evidence that this increased the risk of recurrence, but it would appear that the use of a graft allows earlier detection of a recurrence (Hirshowitz and Mahler, 1971). A graft may therefore be a wise choice for the inexperienced surgeon or where there is doubt as to the adequacy of clearance. Adequate excision under good operative conditions should precede reconstruction of any kind. Failure to achieve this may account in part for the bad reputation of rodent ulcers at the inner canthus. The recurrence rate in this series (3·0 per cent) is very similar to recurrence rates for surgically treated rodent ulcers at other sites (3·0 per cent) (Hayes, 1962). It would seem that recurrence is more likely if

Correspondence to: Department of Plastic Surgery, Bangour Hospital, West Lothian.

excision was incomplete histologically and there may be a relatively long latent period before recurrence becomes evident. Follow-up should be maintained in these cases for at least 10 years. An alternative approach would be to re-operate at an early stage if a report which suggests inadequate excision is obtained. It should be noted, however, that of 17 lesions with an unsatisfactory histological report there have so far been only 3 cases of recurrence. This would indicate that close follow-up rather than immediate re-excision can be acceptable. Similar observations have been made by Pascal et al. (1968) and Golwyn and Kasdon (1978).

Complications following surgery were uncommon. None of the patients has died as a result or from recurrence. None has required exenteration of the orbit. The incidence of epiphora was 9 per cent and appeared to persist in cases where the upper and lower puncta had been excised. In none was the epiphora a problem. Thus, surgical excision of an inner canthal rodent ulcer should not be compromised because of the proximity of this structure. It is debatable whether reconstruction of the nasolacrimal system is absolutely necessary.

Acknowledgements

I am grateful to the consultant plastic surgeons in Canniesburn Hospital for allowing me to study their cases. I would also like to thank Nancy Halleran for obtaining the case records and Evelyn Cruikshank for typing the manuscript.

Book reviews

Modern Perspectives in the Psychiatric Aspects of Surgery

Edited John G. Howells. 240 × 150 mm. Pp. 756. 1978. London: Macmillan. £15·00.

NOT many surgeons will read or refer to this book and in many ways that will be a pity. However, their reluctance may be reinforced by the fact that the book largely comprises psychiatrists' observations on surgery and surgical patients—of its 48 contributors, 34 are psychiatrists (one of them with a surgical fellowship), 5 physicians, 4 psychologists, just 3 (I think) surgeons, 1 dentist and 1 anaesthetist. Perhaps this tells us something about surgeons who, though often sympathetic and warm, are rarely analytic about their patients' mental state or receptive in the formal sense to cries of help from minds in torment. Nevertheless, it seems a pity that psychiatrists have not entered more often into partnerships with surgeons nor savoured a little bit more the views and opinions of those actually involved in surgical care. It would, I believe, have rendered their accounts a little less wordy and sometimes even their conclusions a little more rounded. In particular I find it difficult to see why a physician should write the opening chapter on the ethical objectives of surgery: Dr A. Paton's account is as good as one would expect from him but it clearly does not reflect a deep and intuitive understanding of what makes surgeons 'tick' or the objectives they pursue.

In spite of these general observations, the work is a mine of information for anyone who seeks an entry point into the still largely unmapped terrain of the psychological and social aspects of surgical illness. The historical reviews are for the most part excellent. The bibliography seems to end about 1974 which possibly accounts for a rather superficial account of postoperative delirium and an absence of the recent important work of Devlin and his colleagues on colostomy and ileostomy. These are areas of which I can claim some knowledge and they set one wondering if the same is possibly true of other sections. The production is excellent and the index and referencing exemplary. Definitely a volume for the library shelf and the personal possession of all those particularly concerned with this fascinating interdisciplinary field.

H. A. F. DUDLEY

Gynaecology

Langdon Parsons and Sheldon C. Sommers. Second edition. 270 × 185 mm. Pp. 1660+xxxii. Illustrated. 1978. Eastbourne: Holt–Saunders. £35·00.

THE second edition of this well-established American textbook follows 16 years after the first, and presents the carefully weighed opinions of an emeritus professor of gynaecology and of a professor of pathology. Its approach is thus comprehensive yet conservative and its constant references to pathology give it a diagnostic rather than therapeutic bias.

The arrangement of the sections into the 'ages of woman' is interesting although at times artificial, but the paragraph headings in the form of questions help to hold the reader's attention. In fact the book as a whole is a joy to read and a model of lucid prose.

Should this rather expensive volume of almost 1700 pages find a place on the surgeon's bookshelf? It will not assist him in deciding on the operative management of female surgical patients, but if he is looking for a thorough and thoughtful review of current thinking in gynaecology he will be rewarded. There are certain areas where British and American practices differ (bromocriptine and danazol are barely given a mention), but the very comprehensive references up to 1976 help to make up for any apparent deficiencies in the text. Printing errors are confined to several authors' names in the references and to the unfortunate transposition of the legend to the illustrations of methods of sterilization in *Fig.* 30–5.

D. H. HORWELL

Cancer in China

Edited H. S. Kaplan and P. J. Tsuchitani. 220 × 150 mm. Pp. 240 +xii, with 34 illustrations. 1978. New York: Alan R. Liss Inc. No price given.

WHILE the problems of cancer remain largely unsolved all of us are curious about the work of others. *Cancer in China* appeals to one's curiosity on two scores: first, because it is about cancer and, to a secondary degree, because it is also about modern China itself.

The volume is a report of a visit to the People's Republic of China by a delegation of ten American scientists, a China scholar specializing in geography and a staff officer.

The book starts by detailing the organization of medical care in China and then goes on to describe the cancer research institutes, hospitals and medical colleges visited. The section on epidemiology is of interest, giving tables of occurrence of cancer at different sites and comparing these with figures for the UK and America. The three great Chinese cancer problems, namely nasopharyngeal, oesophageal and liver cancer, are dealt with fully. Comparative methods of early diagnosis and treatment by surgery, radiation therapy and chemotherapy are discussed.

No one would claim that this book gives us a full picture of all that the Chinese know about cancer, but as an edited diary of this group's visit, it makes interesting reading.

G. J. HADFIELD

Radiological Atlas of Biliary and Pancreatic Disease

H. Baddeley, D. J. Nolan, and P. R. Salmon. 260 × 200 mm. Pp. 256, with 297 illustrations. 1978. Aylesbury: H M+M.

THIS compact book sets out to provide an atlas of the radiological appearances of biliary and pancreatic disease. It is timely, since it illustrates beautifully the newer techniques of endoscopic retrograde choledochopancreatography and of fine needle percutaneous cholangiography. The illustrations are of a very high calibre and cover a wide range of conditions, depicting even minor variations in anatomy and in disease. There are few criticisms of the illustrations but one on p. 69 (*Fig.* 6.46) should be omitted since it has not reproduced well and is open to alternative interpretation. The vexed question of papillary stenosis is dealt with and convincing pictures produced of secondary stenotic lesions. However, as in so many other publications, the evidence for primary biliary stenosis and biliary dyskinesia is unconvincing.

The illustrations of the pancreatic duct are of a very high order and are especially valuable in outlining anatomical variations and minor degrees of pancreatic damage seen in chronic pancreatitis.

This book, whilst highly successful as an atlas, does not quite succeed in its second stated aim, namely 'to suggest patterns of investigation which we hope will be of use to radiologists, physicians and surgeons'. There is perhaps too much emphasis on ERCP and less on other methods of investigation and especially ultrasonic display of abnormalities of the biliary tree and pancreas. This is particularly evident in some of the discussions relating to the pancreas and pancreatic cysts. It should perhaps not be expected that an atlas deal fully with complications of investigations or their ordered use, but perhaps some of the dangers inherent in the use of ERCP in acute pancreatitis could have been more fully stated and the real contribution which can be made by less invasive means emphasized.

Despite these minor criticisms, this book fulfils an important role and should find a place on the shelves of all those interested in the niceties of biliary and pancreatic diagnosis and treatment. I concur with the final sentence of the Foreword that the book should be in the library of all centres undertaking the training of radiologists.

SURGICAL PROBLEMS IN THE AGED

Edited by K. D. J. VOWLES, MB, CHB, FRCS,
Consultant Surgeon, Devon and Exeter Clinical Area

Contents: Foreword by Sir Ferguson Anderson; Surgery for the Aged; Assessment before Surgery; Anaesthesia for the Aged; The Problem of Dysphagia; Gastroduodenal Problems; Biliary Tract and Pancreatic Problems; Problems with Hernia, the Small Intestine and the Appendix; Colonic and Rectal Problems; Urological Problems; Problems of the Aged Hip; Vascular Problems and the Aged Amputee; Postoperative Problems in the Aged; Index.

The care of the aged is an increasingly important subject and it is now recognized that surgical care of the elderly patient requires special consideration. This book outlines a wide range of the problems of the aged which require surgery for their solution and indicates how the aged differ in presentation, morbidity and mortality, and how operative and postoperative management may be modified.

QUESTIONS AND ANSWERS IN GENERAL SURGERY
(for revision and self assessment)

H. P. HENDERSON, FRCS, *Senior Registrar, Plastic and Jaw Surgery, Fulwood Hospital, Sheffield;* and M. J. KELLY, MChir, FRCS, MRCP, *Senior Registrar in General Surgery, Bristol Royal Infirmary*

With a Foreword by The Right Hon. the Lord Smith of Marlow, KBE, MS, FRCS

This book contains questions and answers suitable for candidates revising for the Final FRCS Examination in General Surgery. The whole field for the examination is covered including subspecialties. The questions are laid out in random fashion to lessen the tedium of learning section by section and the answers have been placed adjacent to the questions. An index has been provided to enable readers to work through particular sections of their revision if they so wish

You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. —The ubiquitous staph. needs an ubiquitous antibiotic — penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole fucidin

FUCIDIN (sodium fusidate B.P.)
Dosage:
Adults: 500 mg (2 capsules) 3 times daily with food.
Children: 20-40 mg/kg body weight daily in 3 divided doses with food.
The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:
After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.
Product Licence No: 0043/5019.
Each capsule contains 250 mg sodium fusidate B.P.

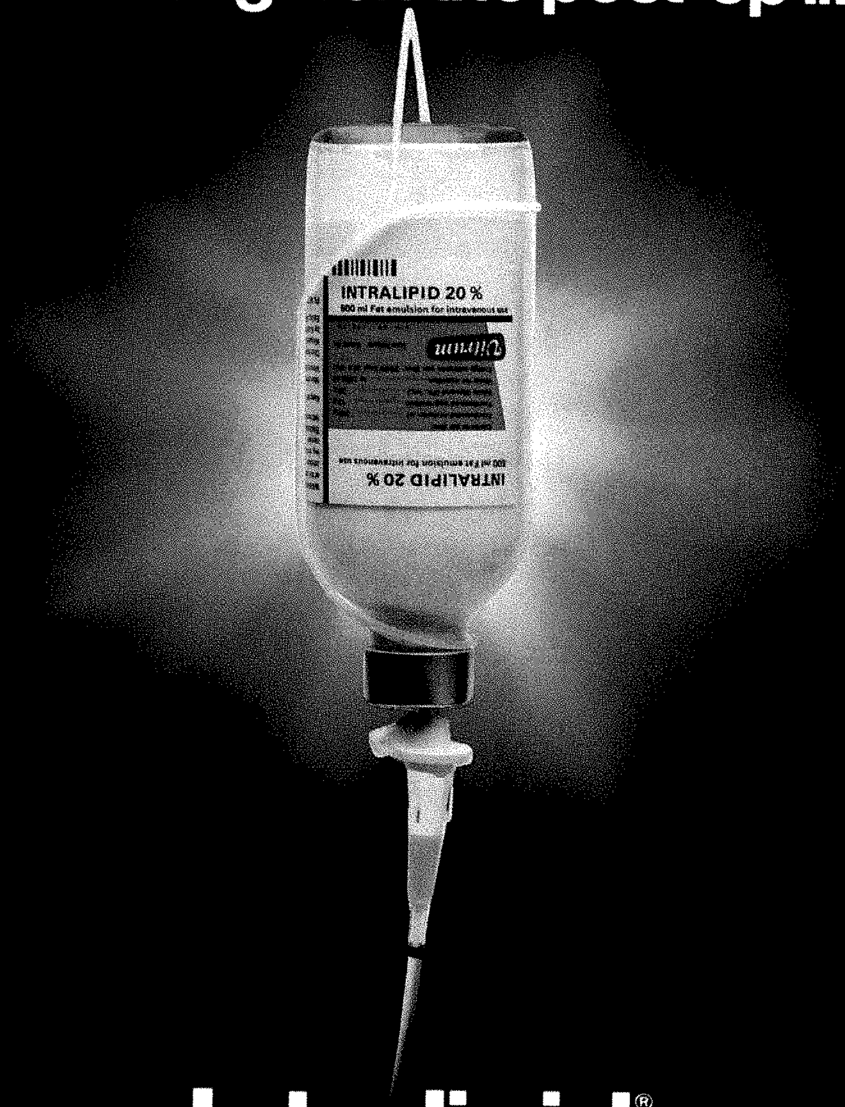
How to strengthen the post-op life line



INTRALIPID 20 %
500 ml Fat emulsion for intravenous use
Vitrum
INTRALIPID 20 %
500 ml Fat emulsion for intravenous use

Intralipid®

soya bean oil emulsion 10% and 20%

the most concentrated source of energy for central and peripheral infusions from the world leaders in complete intravenous nutrition

PRESCRIBING INFORMATION
INTRALIPID 10% INTRALIPID 20%

Presentation A milky white oil-in-water emulsion

	Intralipid 10%	Intralipid 20%
Fractionated soya bean oil	50 g	100 g
Fractionated egg lecithin	6 g	6 g
Glycerol (Ph. Eur.)	12.5 g	12.5 g
Water for injections to 500 ml		

pH 7. The solution is sterile and pyrogen free.

Uses When feeding patients intravenously the possibility of giving a sufficient amount of energy in the form of carbohydrate is limited by such considerations as hypertonicity, hypervolaemia and the tendency to thrombophlebitis. The development of fat emulsions has overcome these problems. Fat has a high energy value (9.3 calories per gram) and by the use of fat emulsions it is possible to provide a high calorie intake in a relatively small fluid volume. Fat emulsions also have a protein sparing effect when given in conjunction with amino acid solutions to [illegible] Intralipid. The intravenous fat emulsion Intralipid is metabolised in the same way and at the same rate as normal chylomicrons. One litre of Intralipid 10% provides 1 100 calories and 1 litre of Intralipid 20% provides 2 000 calories.

Indications Intralipid fat emulsions are indicated in conditions of severe protein depletion requiring also a high energy intake to compensate for excessive loss of calories following trauma, infection, fever, burns, etc.

Dosage and administration Intralipid 10% 500-1 500 ml daily in conjunction with intravenous amino acids. For increased caloric requirements Intralipid 20% 500-1 500 ml daily in conjunction with amino acids. Intralipid 10% and 20% are administered by slow intravenous infusion. During the first 10 minutes the drip rate should be adjusted to 20 drops per minute and after half an hour this can be adjusted to a final rate of 60 drops per minute. 500 ml of either emulsion should be given in not less than three to five hours on the first day of infusion. On the first day of infusion it is advisable to administer 10 ml Intralipid 10% or 5 ml Intralipid 20% per kg body weight. Subsequently the dose is usually doubled, and when a larger intake is indicated it may be increased to 3 g fat per kg body weight.

Infant dosage Intralipid 10% or 20% 15-20 ml per kg body weight in 24 hours.

Contra-indications, warnings, etc. Intralipid is contra-indicated in pathological hyperlipaemia and severe liver damage.

Precautions When daily intravenous fat administration for more than one week is indicated it must be ascertained, in order to prevent the development of cumulative lipaemia, that the patient is capable of eliminating the infused fat from the circulation, and this function can be tested in the following manner. In the morning following the first day's infusion, a citrated blood sample is drawn, preferably when the patient is still in a fasting state. The blood sample is centrifuged at 1 200-1 500 rpm. If the plasma is then strongly opalescent or milky, further infusion should be postponed. In the great majority of cases, plasma is completely clear 12 hours after the conclusion of an infusion of 2 g fat per kg body weight corresponding to 20 ml of Intralipid 10% or 10 ml of Intralipid 20% per kg body weight. This test should be repeated at weekly intervals.

Pharmaceutical precautions Store at a temperature between 4°C and 8°C and do not use after the date of expiry indicated. The contents of each bottle are for a single infusion and any residual emulsion should be discarded. No drugs should be added to Intralipid prior to or during infusion.

Legal category No legal restrictions on sale or supply.

Package quantities Intralipid 10% 100 ml and 500 ml; Intralipid 20% 100 ml and 500 ml.

Further information Nil.

*Constitute the Editorial Committee

Whilst every effort is made by the publishers and editorial committee to see that no inaccurate or misleading data, opinion or statement appear in this Journal, they wish to make it clear that the data and opinions appearing in the articles and advertisements herein are the responsibility of the contributor or advertiser concerned. Accordingly, the publishers and the editorial committee and their respective employees, officers and agents accept no liability whatsoever for the consequences of any such inaccurate or misleading data, opinion or statement.

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, John Wright & Sons Ltd, Broadmead House, 21 Panton Street, London SW1Y 4DR.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the journal unless rights are reserved before publication.

Business communications should be sent to *John Wright & Sons Ltd, British Journal of Surgery, Bristol BS8 1EX.* Remittances are payable to the *British Journal of Surgery.*

Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

Manuscripts

The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

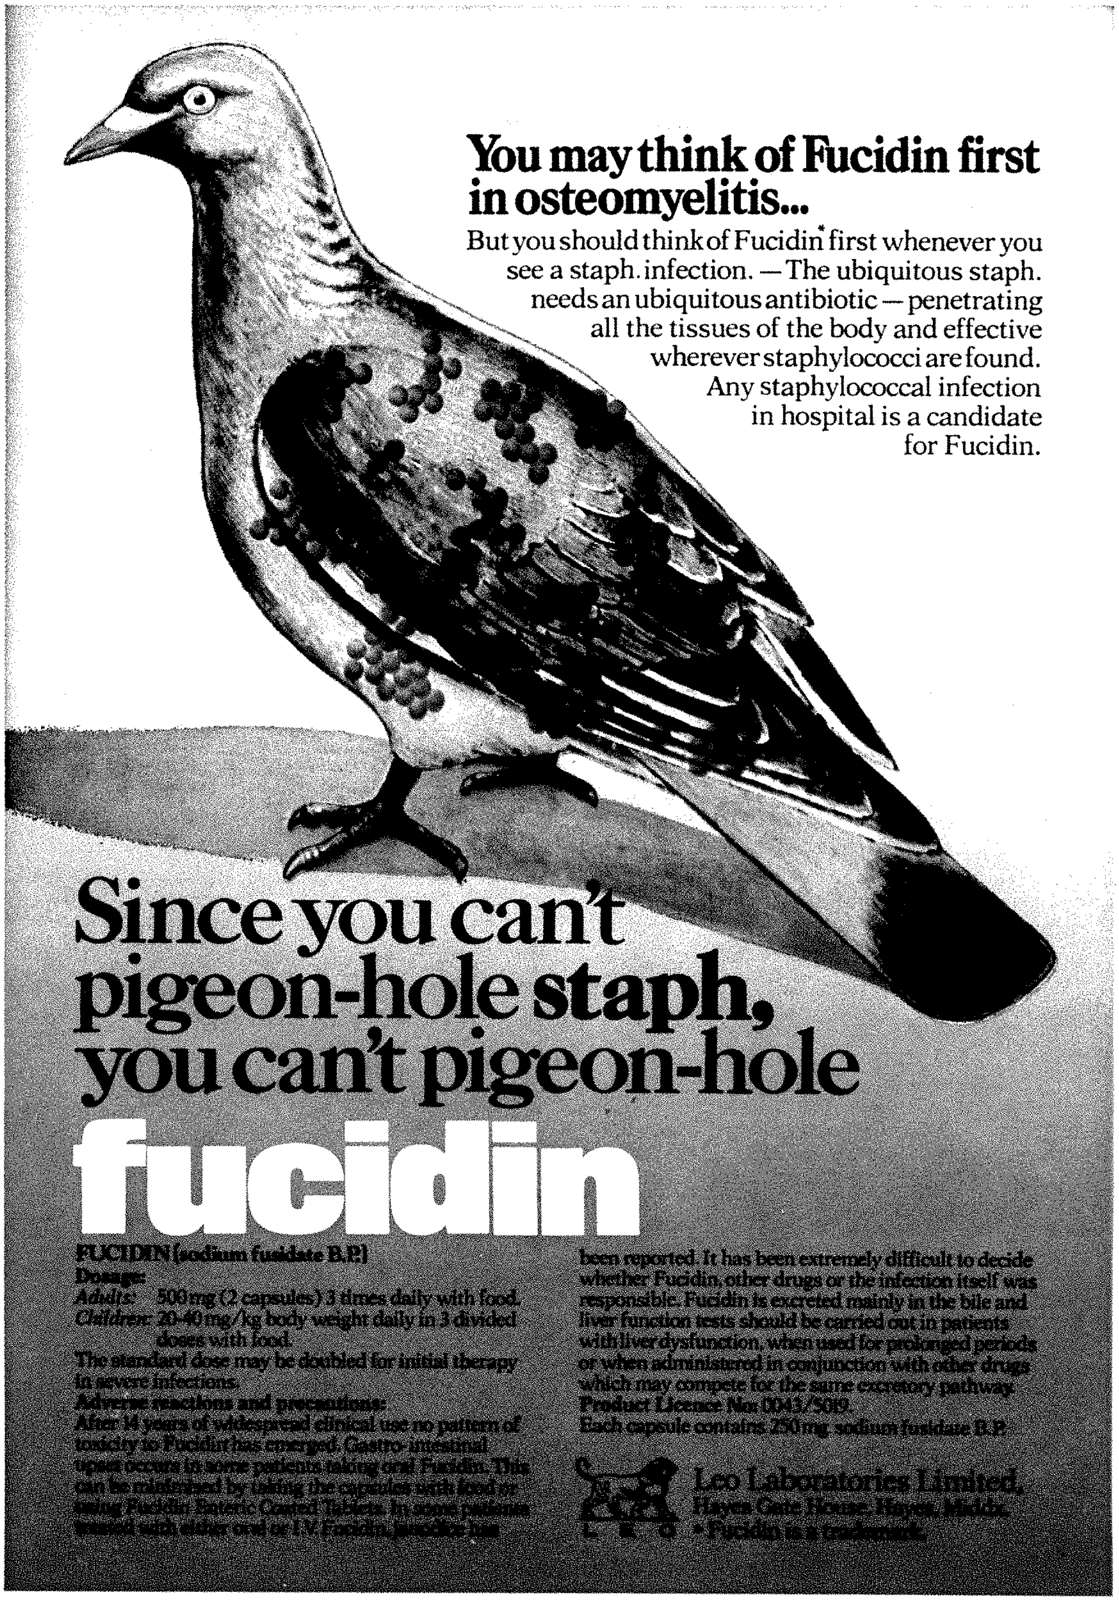
Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations

It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978: **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors.* London, Pitman, 1978.

References

In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus*. Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).



You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. —The ubiquitous staph. needs an ubiquitous antibiotic — penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Benign Breast Disorders

3 studies on Danol

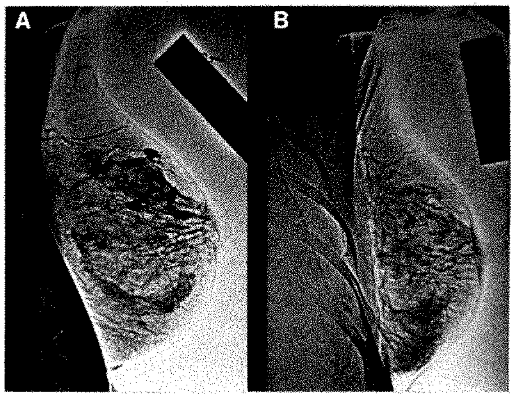
1. "..a marked improvement in both objective and subjective symptoms in 87.5% of patients studied."

(Study of 40 patients given Danol for up to 6 months. Obstet. Gynec. 1976, 48: 93.)

---

2. 75.8% "..experienced complete relief of subjective discomfort with disappearance of clinical signs."

(Study of 58 patients given Danol for between 74 and 310 days. Am. J. Obstet. Gynec. 1977, 127: 130.)



Xeromammograms of patient with intense fibrocystic disease (A) showing marked reduction in breast size and cystic area (B) after 6 months on Danol.

---

3. "..a significant decrease and elimination of breast pain and tenderness ...and elimination of nodules and lumpy areas..."

(Preliminary report on open study of 260 patients given Danol for 4 to 6 months. J. int. med. Res. 1977, 5 (Suppl. 3) 101-108.)

Danol

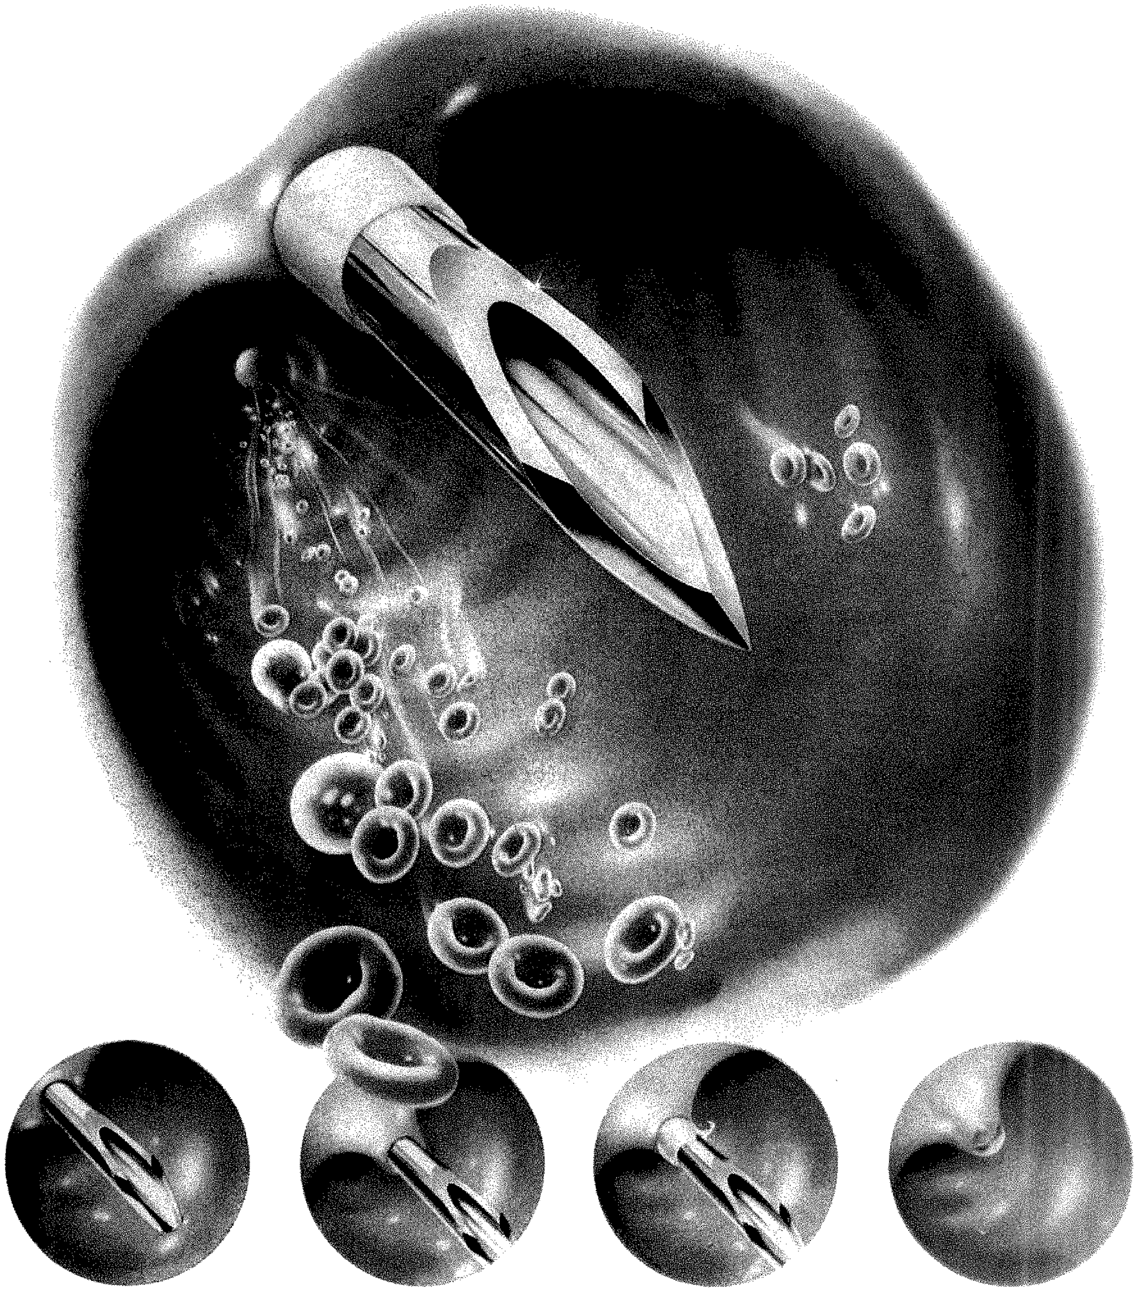
danazol

antigonadotrophic agent without oestrogenic or progestogenic activity

Danol (danazol 200 mg) PL 0071/0095. Bottles of 100 capsules. Basic NHS cost of one day's treatment £1.42 (3 capsules). **Danol-½** (danazol 100 mg) PL 0071/0094. Bottles of 100 capsules. Basic NHS cost of one day's treatment 72p (3 capsules). **Dosage** Adults 200-800 mg daily. See Data Sheet for details. **Contra-indications** Pregnancy. **Precautions** 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop. **Side Effects** Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control. Danol is a trade mark. Clinical reports and full prescribing information available on request from **Winthrop Laboratories,** Surbiton-upon-Thames, Surrey.

WINTHROP

The intravenous difference



Where the distance between the cannula tip and the heel of the needle bevel is too great, there is a risk of piercing the opposite vein wall before the cannula is satisfactorily placed within the lumen. With Abbocath®-T the cannula tip fits snugly behind the heel of the short bevelled needle tip.

An abrupt cannula shoulder requires a high penetration force, leading to tissue and vein trauma, [illegible] and repeat procedures. The electronically formed double taper tip of Abbocath-T requires a minimal penetration force which is constant from cannula to cannula.

A thin cannula shoulder is likely to roll back or shear during insertion, irritating the vein intima and increasing the risk of thrombus formation and emboli. The Abbocath-T cannula tip is smooth and sturdy with no rough edges or thin spots, and never protrudes over the heel of the needle.

Surgical Review 1 J.S.P. LUMLEY AND J.L. CRAVEN

With rapid developments occuring in many surgical fields, and the limited reading time available to most surgeons, it is difficult for them to keep up-to-date with surgical literature beyond a narrow field of interest. This is the FIRST book in a SERIES which has been designed with these facts in mind, and each volume will provide the surgeon with a rapid revision manual, presented in a simple format. The series is also directed at the postgraduate student preparing for his final Fellowship examination.
The subjects are of topical interest – in the first volume they range from microsurgical advances in neurovascular and plastic surgery to current views on burns, herniae and varicose veins.

22 x 14cm 416 pages Illustrated 0 272 79525 9 £9.95net (Paperback)

Primary Management of Hand Injuries J. CAMPBELL SEMPLE

This concise book is designed to assist the casualty officer in the diagnosis, treatment and referral of hand problems in the accident and emergency department. Considerable emphasis is placed on the assessment of X-Rays, injection of local anaesthetic and simple suturing.

Universal Tube Holder

From Downs Surgical.

British Patent No 1 471 609
Designed by Laurence F Tinckler MD, ChM, FRCS, FACS.

For the fast, convenient and comfortable retention of a variety of tubes, catheters and leads used for patient treatment and diagnosis.

☐ **Fast:**
May be positioned immediately. Unique slot-in action ensures its easy application after tubes have been connected.

☐ **Convenient:**
Seven different slot sizes for retaining a wide range of tubes so that the risks of tension, kinking and occlusion are reduced. Tubes can be temporarily released to facilitate nursing procedures.

☐ **Comfortable:**
The flexible base conforms to most anatomical situations. Non-allergenic adhesive. Avoids the discomfort associated with bandages, strapping and anchor-suturing methods of tube retention.
The Universal Tube Holder is packaged in dispenser boxes of 25. Each Universal Tube Holder is double-wrapped and pre-sterilised by gamma irradiation. Catalogue reference BH 010-01-L.

Downs Surgical - simply the best

To: Disposable Products Division, Downs Surgical Limited, Church Path, Mitcham, Surrey, CR4 3UE, England.
Please send me further information and samples of the Universal Tube Holder.

The management of gross refractory obesity by jejuno-ileal bypass

R. M. BADDELEY†

SUMMARY

Jejuno-ileal bypass has been performed in 226 massively obese patients, 190 of whom have been followed for a minimum of 1 year. End-to-side and end-to-end anastomoses were compared and no difference in the weight reduction achieved by either technique was seen throughout the 5-year follow-up. There was no significant difference in weight reduction achieved between groups of patients in which the jejunal length varied from 10 to 35 cm and the ileal length from 35 to 10 cm.

The weight reduction achieved in the entire series averaged 36·7 ± 9·4 per cent at 2 years, after which no further loss occurred. Good psychological benefits were recorded. Remission of diabetes occurred in 12 of 13 patients and marked long term lowering of serum lipids was seen.

Side effects included fluid and electrolyte disturbances and fatty changes in the liver during the first year, improving thereafter. Early cirrhosis of the liver occurred in 8·6 per cent. Other side effects included abdominal bloating, arthralgia and renal colic.

The operative mortality was 0·9 per cent and the late mortality directly attributable to the jejuno-ileal bypass, 3·1 per cent. In 19 patients the bypass was discontinued because of severe side effects.

THE use of small bowel bypass in the management of gross obesity was first reported by Kremen, Linner and Nelson in 1954. Later, Payne and DeWind (1969) found optimal results with 14 in (35 cm) of jejunum anastomosed end-to-side to the terminal ileum 4 in (10 cm) from the ileocaecal valve. Subsequently, other surgeons have varied the lengths of jejunum and of ileum and some have used an end-to-end anastomosis.

In the present series 226 massively obese patients have undergone jejuno-ileal bypass, 190 of them having a minimum follow-up of 1 year. The age range was 16–60 years; there were only 26 males. The criteria for acceptance for the procedure were (*a*) chronic simple obesity of at least 5 years' duration, which had (*b*) proved refractory to properly supervised dietary measures, and which (*c*) amounted to at least 45 kg or 100 per cent above standard body weight for age, sex and height.

Methods

Preoperative assessment

Preoperative investigations were designed to confirm the gross simple nature of the problem by screening for rare endocrine causes such as Cushing's disease and myxoedema, to expose subclinical abnormalities such as diabetes, hyperlipidaemia and deficiency states and to provide baselines for postoperative comparison. In addition, percutaneous liver biopsy was performed when biochemical liver function tests were abnormal.

Surgical techniques

Each patient received conventional bowel preparation and prophylactic antithrombotic therapy. Midline incision was preferred to paramedian or transverse incisions to minimize the duration of the operation. Liver biopsies were taken routinely and gallstones, hiatus hernia and pelvic abnormalities sought. Details of the technique of jejuno-ileal bypass have been described elsewhere (Baddeley, 1977).

Postoperative management

The management of postoperative ileus followed conventional lines of nasogastric suction and intravenous fluids. Profuse diarrhoea started by the third or fourth day but this was satisfactorily controlled with Lomotil (5 mg four times daily) and restriction of oral fluids to 1200–1500 ml daily). An oral potassium preparation was routinely prescribed.

In recent years all post-bypass patients have been placed on a high protein, low fat, low calorie diet of up to 1500 kcal daily. The low fat content lessens the problem of diarrhoea and the high protein intake is aimed at achieving an appropriate protein–calorie balance.

After discharge from hospital most patients have been reviewed regularly and haematological and biochemical profiles obtained. Annual liver and bone biopsies have been performed.

Results

End-to-side v. *end-to-end jejuno-ileal bypass*

The majority of surgeons reporting their experience with jejuno-ileal bypass have found considerable variation in the amount of weight loss achieved. This inconsistency has been attributed by some to reflux of bowel contents into the excluded ileum thereby providing a greater absorptive surface. They have sought to prevent it by end-to-end jejuno-ileal anastomosis, implanting the excluded ileum into the ascending, transverse or sigmoid colon. Scott et al. (1977) reported greater and more consistent weight loss using this technique.

In 1972 this study was commenced to compare the efficacy of the two types of anastomosis. Two groups of patients were randomly assigned to one or other

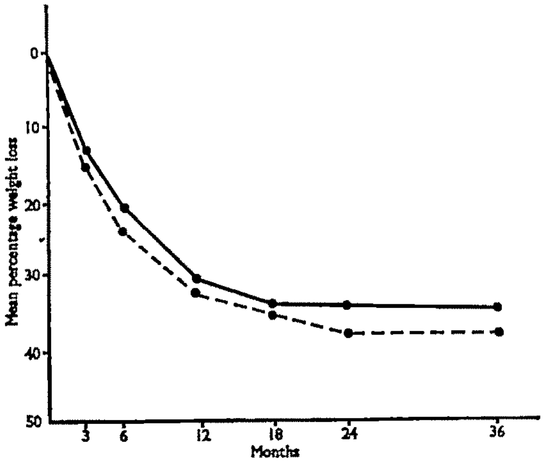

Fig. 2. Comparison of long jejunal segment and long ileal segment jejuno-ileostomy. ●——●, 35 cm of jejunum and 10 cm of ileum ($n = 18$); ● - - - ●, 10 cm of jejunum and 35 cm of ileum ($n = 16$). P value was not significant at any stage.

Table I: MEAN PERCENTAGE WEIGHT LOSS AFTER TWO TYPES OF JEJUNO-ILEOSTOMY

Time (mth)	End-to-side	End-to-end
3	14·2	16·2
6	21·5	23·4
12	31·3	33·6
18	36·2	36·8
24	39·5	37·8
36	37·3	36·0
48	37·8	36·2
60	38·2	36·6

procedure, the lengths of jejunum and ileum retained in enteric continuity being 35 cm of jejunum and 10 cm of ileum in both. The groups were comparable for age, sex and original weight. No significant difference in weight loss was seen during the entire 5-year period of follow-up (*Table I*). The incidence of side-effects was similar in both groups.

These findings conflict with those of Scott et al. (1977) but agree with Gaspar et al. (1976) and Merscheimer et al. (1977). Recently, pneumatosis cystoides intestinalis and bypass enteritis (Passaro et al., 1976) have been reported in patients who had undergone end-to-end jejuno-ileostomy and ileosigmoidostomy. For this reason, and because end-to-side jejuno-ileostomy is a simpler and quicker method, the latter procedure has been preferred since 1973.

Optimal lengths of jejunum and ileum

The lengths of jejunum and ileum retained in continuity are of importance as too much retained bowel results in inadequate weight loss and too little bears the risk of serious nutritional deficiencies. The early clinical studies of Payne and DeWind (1969) suggested that 35 cm of jejunum and 10 cm of ileum gave optimal weight reduction with minimal hazards but some surgeons have subsequently varied these measurements to achieve better and more consistent weight reduction. These variations have been from as much as 40 cm to as little as 10 cm of jejunum and from 50 cm to as little as 4 cm of ileum.

Scott et al. (1977) compared groups of patients in whom bypasses consisted of 30 cm of jejunum but the ileal lengths were variously 30 cm, 20 cm and 15 cm. They concluded that the optimal lengths were 30 cm of jejunum and 20 cm of ileum, shorter lengths being associated with more diarrhoea and metabolic difficulties.

To evaluate further the optimal lengths of small bowel retained in continuity, consecutive patients in this series were allocated randomly to jejuno-ileal end-to-side bypass procedures in which the lengths of jejunum were 35 cm, 30 cm or 10 cm and the lengths of ileum were 10 cm, 15 cm or 35 cm respectively. The percentage weight reduction achieved in each group of patients is shown in *Fig.* 1 which reveals no significant difference between any combination of these dimensions. The incidence of side effects was similar in each. Short lengths of jejunum (10 cm) with long lengths of ileum (35 cm) induced no significant improvement in weight loss than the reverse measurements (*Fig.* 2).

The total length of small bowel in continuity is of importance. Jejuno-ileum measuring 70 cm is associated with little or no weight reduction. Patients with 47 cm of jejuno-ileum lose significantly more weight than those with 50 cm (Baden, 1974; Quaade, 1977). The optimal length of jejuno-ileal bypass thus probably lies between 45 and 50 cm. In view of the importance of balanced protein–calorie nutrition, it may be judicious to retain a longer length of jejunum than of ileum for nutrient absorption and thus the measurements 30 cm of jejunum and 20 cm of ileum are used at present.

Pattern of weight reduction

There being no significant difference in the weight reduction achieved by varying the lengths of small bowel or the type of anastomosis, the results in all groups have been compiled and presented as a pattern of weight reduction in *Fig.* 3. The percentage decline in weight is greatest during the first 6 months (22·0 ± 5·9), reaching 32·4 ± 8·3 by the end of the first year. Thereafter the weight loss slows to 35·4 ± 8·6 per cent at 18 months and 36·7 ± 9·4 by 2 years. Mild weight regain of up to 10–12 kg may occur but most patients learn rapidly to control this by modest restraint of their excessive eating.

Mechanism of weight reduction

Whilst there is no doubt that malabsorption, as evinced by steatorrhoea, occurs after jejuno-ileal bypass, there is evidence that reduced appetite and consequent diminished calorie intake explain adequately the loss of weight achieved (Pilkington et al., 1976; Bray et al., 1977). Weight reduction ceases due to restoration of appetite and adaptive changes in the functioning jejuno-ileum which are manifest as dilatation, elongation and mucosal hyperplasia.

Thus, in the creation of jejuno-ileal bypass there is some logic in utilizing maximal lengths of jejunum and ileum, sufficient to achieve adequate weight reduction and to take further advantage of the spontaneous impairment of appetite by further dietary restraint over the succeeding 18–24 months. The potential hazards of nutritional deficiencies would thereby be reduced, especially if a high protein, restricted calorie diet were adopted.

Beneficial effects

Apart from marked and sustained reduction in excess body weight, the main beneficial effects of jejuno-ileal bypass are reduction of hypertensive blood pressure (Fikri and Cassella, 1974) improved respiratory function (Soterakis et al., 1976), psychological rehabilitation, remission of diabetes and reduction of serum lipids.

Psychological and social benefits: Depression, social limitation, marital disharmony, redundancy and unemployment are common complications of massive obesity. Personality disorders may arise as a result of embarrassment, humiliation, lack of self-esteem, fears of rejection and loss of self-confidence. After small bowel bypass mild optimism and euphoria occur in the expectation of future slimness and good health. The patients become more confident and socially active. They are able to acquire work or cope better with domestic or occupational commitments. Pregnancy has occurred normally and without complication after weight reduction has ceased (Baddeley and Fielding, 1977). At the other extreme, severe psychiatric disturbances have been reported (Abram et al., 1976; DeWind and Payne, 1976), though others have found them to be infrequent (Brewer et al., 1974; Solow et al., 1974; Castelnuovo-Tedesco and Schiebel, 1976).

Diabetes: This complication is three to four times more common in the obese than the slim and can be corrected by weight reduction.

Thirteen of the present series of patients were either already known diabetics (4 patients) or found to be so on routine preoperative assessment by fasting blood sugar and glucose tolerance tests. When reassessed 9–44 months after jejuno-ileal bypass all but one had normal blood sugar levels (*Fig.* 4) and even that one patient showed only mildly raised levels. Glucose tolerance had returned to normal in 8 patients, 4 showed miscellaneous abnormalities of much less marked severity and one retained a florid diabetic type of curve (Fielding and Baddeley, 1978). None of the patients required hypoglycaemic therapy.

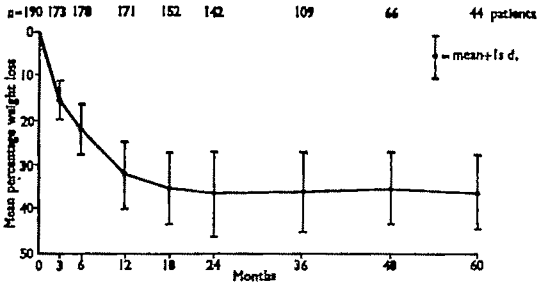

Fig. 3. Mean percentage weight loss after jejuno-ileal bypass.

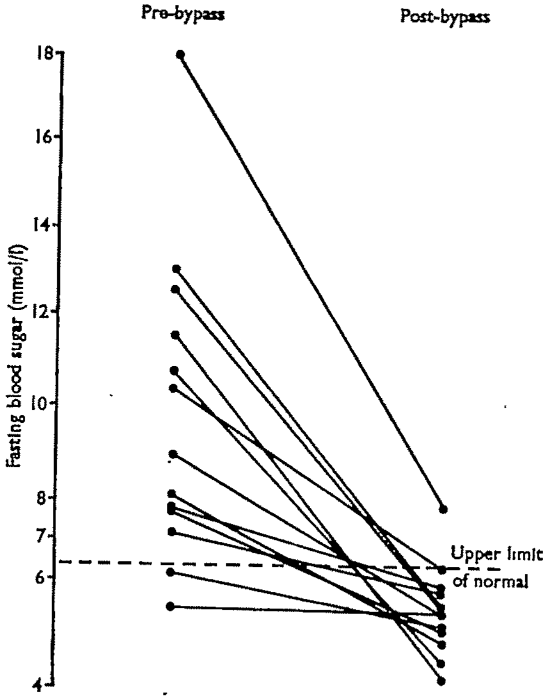

Fig. 4. Changes in blood sugar level before and after jejunal ileal bypass.

Reduction of serum lipids: Jejuno-ileal bypass reduces the amount of mucosal surface available for fatty acid absorption and causes bile acid deficiency by partial interruption of the enterohepatic circulation. As a result of the loss of bile salts in the stool, steatorrhea is further exacerbated. Mobilization of lipids from peripheral stores occurs, allowing a compensatory increase in bile acid synthesis by the liver.

The effects of these changes upon serum cholesterol and triglyceride values are shown in *Fig.* 5. Significant falls were seen during early postoperative months and sustained during the 5-year follow-up period. Reversion of type IV hyperlipidaemia to normal electrophoretic pattern has been a common finding. Similar observations have been made in other series (Scott et al., 1977).

Hazards

Mortality: There have been 2 deaths in 226 patients during the first postoperative month (0·9 per cent). These were due to massive pulmonary embolism and to inhalation of gastric contents, the latter being a case of Praade–Willi syndrome.

Late mortality consisted of 11 deaths, 4 (1·8 per cent) of which were due to myocardial infarction, subacute bacterial endocarditis, acute suppurative pyelonephritis and to accident. In the 7 patients (3·1 per cent) in whom death was attributable to the effects of jejuno-ileal bypass, liver pathology was outstanding. Two patients had cirrhosis (1 alcoholic) and 4 had hepatic failure associated with severe fatty liver. One patient who died from peritonitis following operation to restore bowel continuity because of active urinary tuberculosis, also had a very fatty liver.

This mortality is in keeping with the average incidence of 3·1 per cent (0–11·5 per cent) in 2500 patients culled from the literature by Bray et al. (1977).

Morbidity: The extreme degree of obesity which is prerequisite to the performance of jejuno-ileal bypass purveys an inevitable risk of early surgical complications, such as wound and chest infections, deep vein thrombosis and pulmonary embolism. Liposerous discharge due to fat necrosis in the cut surfaces of the wound is commonly complicated by secondary infection and the likelihood of incisional hernia.

Diarrhoea is inevitable in the early weeks, but the mean stool frequency at 3 months, 4·6 times daily, decreased gradually to 2·8 times daily by 18 months. Excessive diarrhoea of 6 or more stools a day occurred in 25·6 per cent of the patients at 3 months, fell to 12·5 per cent at 6 months and gradually diminished to 6 per cent by 2 years. Such excess was often associated with anal soreness, exacerbation of haemorrhoids or even anal fissure. Most patients overcame the problem by restraint of food and fluid intake together with an antidiarrhoeal.

Fluid and electrolyte deficiencies: During the early months some patients experienced vomiting in addition to diarrhoea and, as a result, developed fluid and electrolyte depletion. Thirty-two patients (16·4 per cent) required admission to hospital for intravenous repletion which was given as a 'cocktail' containing sodium, potassium, magnesium and calcium, administered over 48 h. This was most efficacious in restoring physical and biochemical well-being, but in patients where features of fatty liver were also present parenteral nutrition was instituted until liver function tests returned to normal.

Hypokalaemia: Despite prophylactic oral administration of potassium, 21·8 per cent of patients developed low serum values during the first 6 months, the problem gradually becoming less thereafter as diarrhoea diminished in frequency. Clinical features such as weakness, muscle pain, cramps, nausea and further vomiting were seen in all these cases and were eliminated by repletion. Whole body potassium estimations also revealed low normal values in some patients who were asymptomatic and indicated the need for continued oral repletion for several months.

Hypomagnesaemia was less common in the early months but its incidence gradually increased with time. In many patients the serum values were only marginally low and not associated with symptoms.

Hypocalcaemia occurred in less than 5 per cent of patients in the early months after operation, in contrast to incidences of 20–25 per cent in some reports (Bendezu et al., 1976). Muscle cramps and carpopedal spasm occurred in 4 patients.

Evidence of osteomalacia was sought in routine annual bone biopsies. Of 50 patients followed for 4–5 years, minimal evidence of osteomalacia was found in 5, 1 of whom exhibited symptoms of bone pain and weakness. Demineralization of bone has been reported by Dano and Christiansen (1974) and by Compston et al. (1978), but has not been a feature of other reports.

Abnormal liver function tests were common in the first postoperative year but most, with the exception of alkaline phosphatase, had largely returned to normal by the end of that period (*Fig.* 6).

Acute fatty liver: Only when multiple serum biochemical abnormalities were present were patients liable to exhibit symptoms of anorexia, nausea or vomiting, lethargy and weakness. Liver biopsy showed severe fatty infiltration and, in some patients, cell necrosis.

The acute fatty liver syndrome occurred in 18 patients (*Fig.* 7). Three deaths occurred during treatment by conventional parenteral nutrition regimens and 2 followed operations to restore normal intestinal continuity. These deaths, due to liver failure in 3 and septicaemia in 2, occurred before the report of Heimburger et al. (1975), who showed that parenteral calorie-free amino acid infusion therapy reduced fatty infiltration and repleted the deficiencies of essential amino acids seen by Moxley et al. (1974). Since using the Heimburger regimen, there have been no deaths from this cause.

Altogether 15 patients have responded to parenteral nutrition and 7 have not had further recurrence. Eight patients relapsed and have had normal small bowel continuity restored. Survivors have complete remission of symptoms.

Liver histology: Intraoperative liver biopsies show that 88·4 per cent of the patients had some degree of *fatty infiltration* of the liver parenchyma before jejuno-ileal bypass. The reported incidence has ranged from 65 to 94 per cent (Marubbio et al., 1976).

After jejuno-ileal bypass the severity of fatty change increased in 55·4 per cent of biopsies (*Table II*) but gradually diminished during succeeding years. Even so, by 5 years, 20 per cent of patients still exhibited greater fatty infiltration than that seen on their initial biopsy.

Other postoperative histological abnormalities have included granulomas, portal fibrosis and cirrhosis. Histiocytic granulomas were seen in 16 per cent of 175 patients, being present in the original biopsy of 4 of them. They have varied in frequency from time to time in the same patients, but their significance is not understood.

Early micronodular *cirrhosis* was seen in 4 patients who were biopsied during routine investigations of their obesity or at the time of the intended jejuno-ileal bypass. All of them were, therefore, rejected and the bypass was not performed. Of the 175 patients who have undergone at least one postoperative annual liver biopsy, 15 (8·6 per cent) have subsequently developed early micronodular cirrhosis.

Table II: CHANGES IN HEPATIC FATTY INFILTRATION AFTER JEJUNO-ILEOSTOMY

Year	No. of patients	No change	Improved	Worse
1	132	38	41	73 (55·3)
2	103	25	32	46 (44·7)
3	81	22	28	31 (38·3)
4	44	13	21	10 (22·7)
5	25	9	11	5 (20·0)

Figures in brackets are percentages.

Three deteriorated and have died following discontinuance of the bypass, 2 from liver failure and 1 from hepatorenal syndrome.

The histological features of cirrhosis were recognized at 1 year in 6 patients, at 2 years in 2, at 3 years in 4, in the fifth year in 2 and the sixth year in 1. In only 2 patients could alcoholism have been incriminated as an aetiological factor. Apart from 5 of these cirrhotic patients, each of whom had undergone restoration of small bowel continuity, none has exhibited symptoms or signs of cirrhosis. All have been reluctant to consider reoperation and have been treated by high protein diet and total abstinence from alcohol. Annual biopsies have not revealed further deterioration but should any indication of this occur, it is proposed to discontinue the bypass.

There have been other reports of cirrhosis following jejuno-ileal bypass (Marubbio et al., 1976). Soyer and his colleagues (1976) showed that the cirrhotic change was reversible if small bowel continuity was restored. Disappearance of cirrhotic features was seen in one patient in the present series without reversal of the shunt.

Abdominal bloating: A common complaint after the first year has been abdominal bloating, often associated with embarrassing flatus. Passage of the latter provides some relief but the distension, which usually occurs after large meals, gradually passes off spontaneously over a few hours.

Of 109 patients who replied to a questionnaire, 67·6 per cent complained of this discomfort to a greater or lesser degree. Fifty-six per cent admitted that it was almost always associated with excessive and/or irregular eating habits and that reduction of intake to more normal amounts avoided the problem. Forty per cent found no such benefit, but in these both the distension and the flatus could be controlled with repeated courses of tetracycline or metronidazole. Such treatment unfortunately carries the risk of bacterial resistance and has been used only where all else failed.

The cause of the distension is overgrowth of obligate anaerobes which evoke marked gaseous dilatation of the colon (Barry et al., 1977).

Polyarthralgia and polymyalgia: Multiple small and large joint pains, often simulating rheumatoid arthritis, occurred to a varying extent in 42·4 per cent of 139 patients whose duration of follow-up was 2–6 years. It was severe in 11 per cent and 2 patients required discontinuance of the bypass.

Bouts have usually lasted 1–4 days and have occurred without obvious provocation. The symptoms in some were severely incapacitating and distressing but most frequently the condition is mild and transient. There were no joint changes seen on physical or radiological examination. Serological tests

Fig. 7. Fate of 18 patients suffering from acute fatty liver.

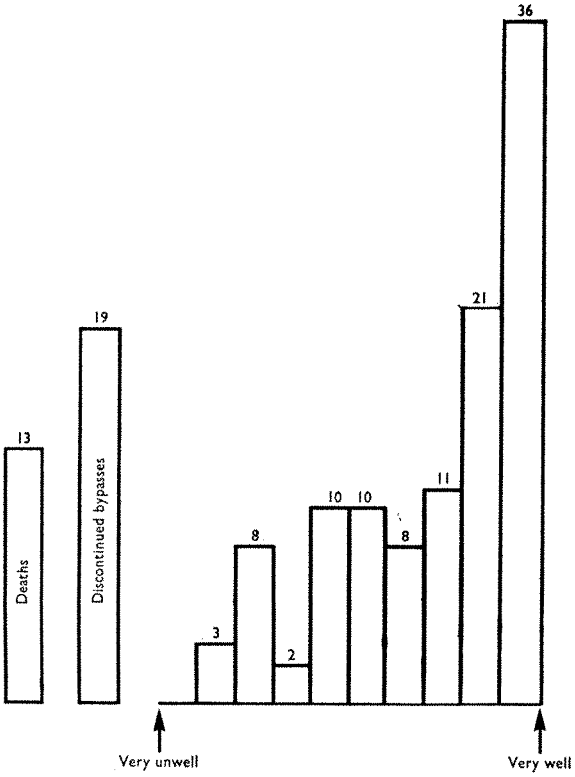

Fig. 8. Subjective state of well-being after jejuno-ileal bypass.

for rheumatoid arthritis, lupus erythematosus cells and antinuclear factor were always negative.

Symptoms usually responded to cotrimoxazole or metronidazole and analgesic after 48–72 h. This indicates an infective cause and evidence in support has been produced by Wands et al. (1976), who showed the presence of circulating cryoprotein immune complexes and complement activation suggestive of systemic absorption of intestinal bacterial antigens, presumably from colonization of the bypassed small bowel.

Other series have reported the occurrence of these side effects in up to 16 per cent of patients (DeWind and Payne, 1976; Wands et al., 1976).

Renal and biliary calculi: Renal calculi of oxalate type have been reported in as many as 30 per cent of patients after jejuno-ileal bypass (Bray et al., 1977). Most surgeons have found the incidence of renal calculi to be 5–10 per cent, and in the present review 5 per cent of 139 patients followed for 2–5 years suffered this side effect. There was, however, no evidence of permanent renal damage in any patient.

Prevention of further renal oxalate calculi by a low oxalate diet has been totally effective in the 7 patients so affected. Alternative treatment would be cholestyramine administration, low fat diet or oral supplements of calcium or taurine.

Although an increased incidence of biliary calculi after jejuno-ileal bypass has been reported (Wise and Stein, 1975; DeWind and Payne, 1976; Merscheimer et al., 1977), it is difficult to substantiate in uncontrolled series of patients who, by the nature of their obesity, are prone to gallstone formation. Studies of bile composition and its lithogenic index (Wise and Stein, 1975; Barry et al., 1977) suggest that biliary calculi would be most likely to occur during the first 6 months after bypass, but thereafter such changes revert to normal.

In the present series there has not appeared to be any excessive incidence of biliary calculi.

Vitamin B12 absorption: Impaired absorption of vitamin B12 has been reported in a number of series (Barry et al., 1977) and is partly due to the short length of ileum available and to bacterial colonization of the small bowel. The pattern of change in serum vitamin B12 levels in the present study has been one of decline to low normal values during the first 18 months, but stabilization thereafter. Only 7 patients in the series developed subnormal values.

Small bowel reconstitution

Because of serious or excessive side effects 19 patients have undergone reoperation to restore normal small bowel continuity. There were 4 deaths, all in patients suffering from liver complications.

The commonest and most serious indication for discontinuance of the bypass was acute fatty liver where incipient liver failure was present (7 patients). Early cirrhosis detected on routine annual liver biopsy has been a further indication for discontinuance of the bypass (3 patients). Other indications have occurred in patients where the discomforts of non-hazardous side effects outweighed the benefits of weight loss. These have included arthralgia (2 patients) and excessive diarrhoea (3 patients). Four patients have undergone discontinuance of the bypass for vomiting, abdominal distension, depression or giddiness. In all cases, small bowel reconstitution has resulted in complete remission.

Subjective benefits of jejuno-ileal bypass

In view of the large number of major and minor side effects encountered, a questionnaire was circulated to 139 patients who had been followed for a minimum period of 2 years. (Nineteen patients who had undergone discontinuance of the bypass and 13 who had died were obviously excluded.) There were 109 replies. Some of the questions and responses were as follows:

Howwell do you feel now as compared with before the operation? 14 worse, 16 no change, 79 better.

Was it worth undergoing the operation? 3 not worth it, 103 worth it, 3 don't know.

To assess the state of well-being, each patient was asked to mark on a straight line with the extremes labelled 'very unwell' and 'very well', where they felt themselves to be. The replies are shown in *Fig.* 8.

It can be seen that the large majority of patients felt subjectively much benefited by jejuno-ileal bypass despite the various side effects which affected some patients to a varying degree.

Conclusions

It is apparent that jejuno-ileal bypass is an effective method of inducing and sustaining weight reduction in the massively obese when all other techniques have failed. Unfortunately, there are a number of associated side effects, some of which are hazardous to life. There is a low operative mortality (0·9 per cent) but a later mortality of 3·1 per cent, which has been mainly due to liver failure. In the main, however, survivors appear to be gratified by the results of the procedure.

It is clear that careful case selection is imperative. Patients who are below average intelligence, alcoholic, suffering from psychiatric illness, cirrhosis, renal failure, symptomatic heart disease or over the age of 50 years should be excluded. On the other hand, those suffering from well-recognized complications of massive obesity such as diabetes, hypertension and osteoarthritis are acceptable if other basic criteria of selection are fulfilled. Good patient discipline and cooperation are essential and there must be a commitment to follow the instructions and advice of the clinician regarding follow-up, diet and discontinuance of the bypass when this is deemed advisable.

In contrast to the iatrogenic malabsorption created by jejuno-ileal bypass, other surgical techniques for reducing massive obesity—dieting enforced by dental splintage and gastric bypass—are effective by physically preventing overeating. Dental splintage depends on satisfactory dentition and proper motivation to sustain the fluid diet regimen over a period of several months. Of 53 patients managed in this manner by the author, 42 were successfully treated with virtually no side effects over a period of 6 months, losing an average 4·12 kg per month (43·7 per cent of mean excess weight). Thus the weight reduction can be as good or better than that achieved by jejuno-ileal bypass. However, it is very doubtful if the long term results will be sustained as these patients are likely to resume their bad eating habits sooner or later after the restraint of dental splintage has been removed.

Gastric bypass has been used increasingly as an alternative to jejuno-ileal bypass during the present decade. In this procedure a high gastric transection is performed to create a fundic pouch of approximately 150 ml capacity, which is drained by a gastrojejunostomy. The stoma of the latter must not be greater than 1·2 cm in diameter. Using this technique Hermreck et al. (1976), Alden (1977) and Griffin et al. (1977) have all shown weight reduction comparable with that achieved by jejuno-ileal bypass. It remains to be seen whether this is sustained over the long term.

Gastric bypass is technically much more difficult than jejuno-ileal bypass and it is to be expected that the operative mortality will be higher, owing mainly to anastomotic leakage. Early problems due to vomiting are more frequent and there are 2–3 per cent incidences of stomal ulcer and dumping. The latter side effects, however, are much less troublesome than those after jejuno-ileal bypass; there do not appear to be any problems from arthralgia, renal colic or abdominal distension and there is much less hazard to the liver.

Thus, jejuno-ileal bypass is the easier procedure with a lower operative mortality. It has a greater morbidity than gastric bypass and requires closer and more detailed follow-up. On balance, the optimum regimen of management for gross refractory obesity may be weight reduction by dental splintage to an 'operable' level of say 30–40 per cent excess weight, followed by gastric bypass. For patients with poor dentition or those likely to be harmed psychiatrically by severe restraint upon eating, jejuno-ileal bypass is an effective alternative now that its side effects are better understood.

Muscle and serum adenosine triphosphatase in patients suffering from tetanus

K. M. SINGH, D. SAWHENY AND N. K. KAPOOR*

SUMMARY

Serial estimation of muscle and serum adenosine triphosphatase (ATPase) activity was performed in 16 healthy control patients and 32 cases with tetanus. There was no significant difference due to age and sex in muscle and serum ATPase activity between the normal and tetanus cases. Tetanus patients showed a marked increase in muscle and serum ATPase activity as compared to normal. The ATPase activity increased with the severity of convulsion and disease. There was increased mortality in tetanus patients having higher values of muscle and serum ATPase.

THE severe muscular contractions of tetanus cause physiological disturbances in the body. Changes in acetylcholine and catecholamine levels were shown in experimental tetanus (Mikhailov, 1969, 1971). Muscle acetylcholinesterase has been reported to be lowered in experimental tetanus (Harvey, 1939; Diamond and Mellanby, 1970). The role of adenosine triphosphatase (ATPase) in muscle contraction is well known (Engelhardt and Ljubimowa, 1939; Szent, 1947). Activation of muscle and brain ATPase in mice by tetanus intoxication was reported by Asakura et al. (Asakura et al., 1951; Asakura et al., 1958a, b). There is no published similar study in human beings. It was, therefore, considered of interest to study muscle and serum ATPase in tetanus patients and the results are described below.

Patients and methods

A total of 16 healthy controls (10 males and 6 females varying in age from 10 years to 40 years) and 32 cases of tetanus (20 males and 12 females varying in age from 5 years to 50 years) admitted to King George's Medical College and Hospital, Lucknow, have been studied. Cases of tetanus in the newborn and in infants have been excluded from the study. The severity of tetanus has been graded according to the classification of Patel and Joag (1959).

The blood sample and muscle from the gastrocnemius were taken at the time of doing venous cutdown before administering any treatment. Estimations of serum and muscle ATPase activity were performed using the method of Kielley and Kielley (1951). Inorganic phosphate was estimated in the protein-free filtrate by the method of Fiske and Subbarow (1925) and protein estimated by the method of Lowry et al. (1951).

Results

No significant difference was observed in muscle and serum ATPase activity in normal control and tetanus cases with regard to age and sex (*Tables I* and *II*). ATPase activity of muscle and serum was found to be increased in tetanus patients when compared with controls ($P<0·01$, by Student's *t*-test after analysis of variance) (*Tables I* and *II*). The increase in muscle ATPase activity was 55·4 per cent and in serum ATPase activity 44·7 per cent, respectively (*Fig.* 1). With increasing severity of convulsions there was a significant increase in muscle and serum ATPase activity in tetanus patients (*Table III*). The severity of tetanus is directly related to the muscle and serum ATPase activity ($P<0·01$) (*Fig.* 2, *Tables I* and *II*). Values of muscle and serum ATPase activity were higher in those who died than in those who survived (*Table IV*).

Discussion

Asakura et al. (1958a, b) have studied the mode of action of tetanus toxin, ATPase activation by tetanus intoxication and specificity of the ATPase. They found ATPase activation in muscle and brain of tetanus-toxin-intoxicated mice. In the present study it has

Table I: MUSCLE ATPase ACTIVITY IN CONTROL AND TETANUS PATIENTS

Died	16	120·50±1·9	58·00±1·10

Values are expressed as mean±s.e. mean μmol inorganic phosphate/g protein/20 mt.

been clearly demonstrated that there is a marked increase in muscle and serum ATPase activity in tetanus patients as compared with normal controls. Neither muscle nor serum ATPase activity were affected significantly by age or sex, both in controls and in tetanus patients. Asakura et al. (1958a, b) have shown that in experimental tetanus the rate of activation of enzyme closely parallels the severity of symptoms regardless of whether the condition is proceeding or in remission. The present study shows a significant increase in muscle and serum ATPase activity with increasing severity of convulsions and disease.

Influence of thyroid surgery on voice function and laryngeal symptoms

STEEN WATT-BOOLSEN, MOGENS BLICHERT-TOFT AND
ARTHUR BOBERG*

SUMMARY

A comprehensive examination of voice function and laryngeal symptoms was applied systematically to 20 patients undergoing thyroid surgery. Patients were excluded from the series if there had been previous neck surgery, or if postoperative indirect laryngoscopy showed abnormal cord mobility. Examination before operation showed that patients with sporadic non-toxic goitre or medically pre-treated toxic goitre had impaired voice function based on stroboscopy, electroglottography, phono-oscillometry and determination of voice range, phonation time, pitch, and peak flow. Three months after thyroid surgery the voice function was significantly improved although not normal in non-toxic goitre patients, whereas the voice function in patients with thyrotoxicosis was unchanged. The number of laryngeal symptoms was significantly reduced in non-toxic goitres following surgery and unaltered in the group with thyrotoxicosis.

THYROID surgery and laryngeal function are intimately associated because of the anatomical relations between the gland, larynx and supplying nerves. Laryngoscopy is recommended to evaluate vocal cord mobility after thyroid surgery (Leading Article, 1977), but is insufficient to detect minor, but none the less important, changes in the vocal function of the larynx. More refined methods are required (Watt-Boolsen et al., 1977). When advocating surgical treatment of thyroid diseases, the possible influence on voice function is of great concern. Remarkably, detailed knowledge of this subject is lacking.

In our study, a comprehensive examination of voice function and laryngeal symptoms has been carried out systematically in patients undergoing thyroid surgery.

Patients and methods

Twenty patients, of whom 16 were female and 4 male, aged between 18 and 72 years with a median of 34 years, underwent thyroid surgery. Twelve patients had a sporadic non-toxic goitre and 8 had a medically pre-treated toxic goitre. At the time of operation all patients were euthyroid clinically and biochemically as judged by serum thyroxine, serum tri-iodothyronine, serum TSH and T_3-resin uptake tests. None gave a history of voice trouble preceding the development of their thyroid disease. The only criterion for exclusion was previous neck surgery and the development after operation of abnormal vocal cord mobility as judged by indirect laryngoscopy.

Operative procedure

A transverse collar incision was made approximately 3 cm above the suprasternal notch and mid-portion of the clavicle on each side. Upper and lower skin flaps were developed by sharp dissection in a plane of cleavage between the platysma and the fascia covering the strap muscles. The strap muscles were separated in the midline and retracted laterally thereby exposing the thyroid gland. The middle thyroid vein and the vessels at the superior pole were divided and ligated on the side to be resected, whereas the inferior thyroid artery was spared. The recurrent laryngeal nerve was not deliberately identified in any instance. A suction drain was brought out through the lateral angle of the wound. All operations had an uneventful course and no wound complications occurred. Indirect laryngoscopy was normal preoperatively as well as on the fifth postoperative day in all cases. The patients with thyrotoxicosis had a sub-total resection of each lobe. Of the patients with sporadic goitre, 3 had a bilateral resection of a multinodular goitre and 9 a unilateral resection of a single nodule. The weight of the removed tissue varied between 6 and 175 g, with a median of 29 g. The weight of removed tissue did not differ significantly between the two groups.

Table I: SCORE SYSTEM FOR EVALUATION OF VOICE FUNCTION

Parameters	Results	Score
Stroboscopy	Regular	1
	Irregular	0
Electroglottography	Regular	1
	Irregular	0
Phono-oscillometry	Regular	1
	Irregular	0
Voice range (semitones)	≥24	3
	24–19	2
	18–13	1
	≤12	0
Phonation time (s)	≥20	3
	19–15	2
	<15	1
Pitch (semitones)	≥7	2
	6–5	1
	<5	0
Peak flow (% of normal peak flow)	≥75	1
	<75	0
Maximum score		12

All patients remained euthyroid during the period of study. Hypoparathyroidism did not occur a sjudged by serum calcium determinations.

Vocal procedures

The voice function was studied the day before operation and 3 months postoperatively. The examination consisted of stroboscopy, electroglottography, phono-oscillometry and determination of voice range, phonation time, pitch and peak flow. A description of the parameters has been given in a previous study (Watt-Boolsen et al., 1977). Furthermore, the following laryngeal symptoms were registered: a frequent urge to clear the throat and/or to cough, excessive dryness of the throat, an easily fatigued voice, a feeling of a lump and/or tension in the throat and, finally, a feeling of respiratory strain.

The objective data were transferred to a score system described elsewhere (Watt-Boolsen et al., 1977) and given in *Table I.* The normal values of voice range, phonation time, pitch and peak flow are the minimal values found in 700 normal persons examined in our laboratory.

Statistical procedures

The Wilcoxon test was used for paired data and the Mann–Whitney U test for unpaired data. Exact confidence limits were used when comparing patient groups with the normal group. $P<0\cdot05$ was considered significant.

Results

Prior to operation a comparison between our two groups of patients and the normal group showed that both the non-toxic goitre patients and the patients with pre-treated thyrotoxicosis had a significantly impaired voice function based on the score system. A comparison between the two groups themselves showed no significant difference in voice function or in the number of laryngeal symptoms.

The scores obtained before operation and 3 months after operation are presented in *Table II* and the number of laryngeal symptoms in *Table III*. Indirect laryngoscopy was normal in all cases both before and after operation.

After surgery it was found that the voice function of the non-toxic goitre patients was significantly improved, although still significantly different from normal. The number of scores was increased in 9 patients, unchanged in 2 and decreased in 1 patient. Furthermore, a significant reduction in the number of laryngeal symptoms was noted. On the other hand, in the group with thyrotoxicosis neither the voice function nor the number of laryngeal symptoms was significantly altered after operation.

Discussion

The causes of impaired voice function in patients with benign goitres are not well established. Restricted mobility of the larynx and compression of supplying nerves may be causative factors (De Gandt, 1970). In fact, this assumption is supported by our findings of improved voice function and reduced laryngeal symptoms in the non-toxic group. On the other hand, in our patients with thyrotoxicosis the voice function and laryngeal symptoms were unaltered by surgery, indicating that factors other than purely mechanical ones are involved. The existence of specific disturbances of voice in untreated thyrotoxic patients has been postulated, but not established with certainty (Luchsinger and Arnold, 1949; Kittel, 1969); it was not made clear whether or not treatment with antithyroid drugs improved the phenomenon. The failure to improve voice function and the persistence of laryngeal symptoms in our patients with thyrotoxicosis should be evaluated in the light of this work.

We conclude that surgical management of benign thyroid diseases can be advocated without the fear of causing voice problems provided that a skilful and delicate technique is observed.

Lingual thyroid: a review of 12 cases

M. R. KAMAT, J. N. KULKARNI, P. B. DESAI AND D. J. JUSSAWALLA*

SUMMARY

Twelve patients with lingual thyroid are reviewed. Two of these patients had a follicular carcinoma in the ectopic gland and both are well 5 and 16 years after treatment.

The diagnosis is essentially clinical but confirmation may be made with a thyroid scan.

Six patients were treated conservatively with thyroxine with good results. Six patients were treated by surgical excision, 2 undergoing autotransplantation of the excised gland into the anterior abdominal wall.

LINGUAL ectopia of the thyroid gland is a rare congenital anomaly caused by failure of the thyroid duct to migrate from the foramen caecum to the usual pre-laryngeal site. Hickman (1869) was the first to describe the condition when reporting the case of a female neonate who died of suffocation from a lingual thyroid 16 h after birth. Since then sporadic case reports have appeared in the literature with an extensive review by Montgomery in 1936. Although Krishnamurthy and Blahd (1972) recorded that 373 cases of lingual thyroid had been reported in the world literature, there has been no recent series published in the British literature.

Carcinoma developing in a lingual thyroid is exceedingly rare and Fish and Moore (1963), in an exhaustive review, could find only 21 published cases. Recently, we encountered two cases of lingual thyroid, one of which was found to be malignant, and this led us to review our hospital records.

Patients and methods

The case records of patients attending the Tata Memorial Hospital, Bombay, between January 1961 and December 1974 were reviewed. Twelve patients with a lingual thyroid had been seen in addition to 4045 patients with thyroid enlargement.

Nine of the patients were female. The age of distribution is shown in *Fig.* 1, the majority of the patients presenting in the second or fourth decades of life.

Symptoms

All the patients complained of dysphagia and an awareness of a foreign body in the throat. Six complained of a change in the quality of their speech. A cough when lying down was the other common symptom. Bleeding from the gland was the main problem in 1 patient. In 3 patients the symptoms appeared to have been precipitated by pregnancy. Duration of the symptoms ranged from 1 week to 6 months although 2 patients had been aware of an asymptomatic swelling for many years.

Diagnosis

The diagnosis was mainly clinical and was made by the characteristic appearance of a swelling in the region of the foramen caecum (*Fig.* 2). The swelling was fleshy, sessile and sometimes ulcerated.

In 8 patients the diagnosis was confirmed by radioactive iodine scan which showed concentration of the isotope at the base of the tongue and absence of isotope in the neck (*Fig.* 3). In one patient additional thyroid tissue was shown at the level of the hyoid.

Treatment

Six patients were treated conservatively with thyroxine. One of these patients has been lost to follow-up. The other 6 patients were treated operatively because of the severity of symptoms associated with recent enlargement and the inability to exclude malignant change.

LIBRARY

Technique of operation

A preliminary temporary tracheostomy was performed so as to avoid possible obstruction of the airway from oedema of the base of the tongue and larynx in the postoperative period. The lingual arteries were ligated on either side of the neck through separate skin incisions at the level of the cornu of the hyoid bone. After inserting stay sutures on either side, the tongue was then cut along the midline fibrous septum (*Fig.* 4). Bleeding was minimal if the incision was kept strictly in the midline.

The tongue was then pulled forward and the lingual thyroid excised. The thyroid tissue is partly in the substance of the tongue and excision in depth is necessary. The tongue was then sutured with chromic catgut and a piece of the gland sent for frozen section histological examination. If there was no evidence of malignancy the excised thyroid tissue was sliced into thin sections and implanted within the anterior rectus sheath.

Results

In 5 of the 6 patients who had conservative treatment the symptoms were controlled, the follow-up ranging from 3 to 10 years. One patient was lost to follow-up, however, and the outcome is unknown.

Of the 6 patients who underwent operation, 2 were found to have a follicular carcinoma of the lingual thyroid. One of these patients, a boy of 12 years, has already been reported (Potdar and Desai, 1971) and he remains well 16 years after treatment with thyroid replacement therapy.

The second patient with a follicular carcinoma was a 40-year-old woman who was shown to have residual thyroid tissue at the base of the tongue by an ^{123}I scan performed after the operation. This was ablated with radioactive iodine and the patient is well 5 years later with thyroid replacement therapy.

The remaining 4 patients had a benign lingual thyroid. Implantation of the excised thyroid tissue into the anterior rectus sheath was performed in 2 patients. The third patient did not need implantation because of the presence of normal thyroid tissue in the neck. Implantation was not performed in the fourth patient for unknown reasons. Two of these 4 patients, 1 who had thyroid implantation and 1 who did not, developed myxoedema and required supplementary hormone therapy. The cause of failure of autotransplantation in 1 patient is not known.

Discussion

Although rare, lingual thyroid may be more common than suggested by the literature, as generally only symptomatic patients will present to the doctor. Of all reported patients 70–80 per cent are female. Our series confirms this sex difference, the cause of which is uncertain. It may possibly be associated with a higher physiological demand in women during puberty and pregnancy, causing hypertrophy. The two peaks

in the age incidence in our series would support this suggestion.

Treatment of a lingual thyroid depends on the severity of symptoms, the age of the patient, any precipitating factors such as puberty or pregnancy and any complicating factors such as ulceration or haemorrhage. There is also a possibility of malignant change, of which there are no characteristic features. This complication, however, is no more likely than in a normally located thyroid.

Lingual thyroids which are small and asymptomatic can safely be kept under observation without any active treatment, as in 70 per cent of cases the lingual thyroid is the only functioning thyroid tissue (Fish and Moore, 1963). Patients with mild symptoms can be treated with thyroxine until the symptoms disappear. Reduction in the size of the gland is quite slow with thyroxine treatment and no dramatic result should be expected. Six patients in this series who had milder symptoms were treated with thyroid hormone with satisfactory results, although the follow-up period is not long. This has been reported by O'Dell et al. (1959). Patients with severe obstructive symptoms, suspected malignant change, ulceration and haemorrhage or who do not respond to hormonal treatment should undergo surgery.

In our patients we have used an intraoral approach to the ectopic thyroid which we think is simpler than the lateral pharyngotomy approach advocated by Hillness and Black (1976). Autotransplantation of the excised gland into the rectus muscle has been advocated by Swan et al. (1952), Lawson (1957) and Jones (1961). Braunwald and Hufnagel (1958) have shown that the site of transplantation of the thyroid is not of primary importance in tissue survival and the rectus muscle is selected because of the easy access.

In the immediate postoperative period the autotransplanted thyroid tissue may not function well and the patient may have temporary hypothyroidism. These patients should not receive thyroxine, however, or there will be suppression of endogenous secretion of thyroid hormone. Ablation of lingual thyroid tissue with radioactive iodine has been recommended by Schilling et al. (1950) but no immediate relief of symptoms is possible with this method and most of these patients develop late myxoedema. It should be stressed, however, that all patients with lingual thyroid, whether treated conservatively or by surgery, need continued close assessment of their thyroid function.

Two patients of the 12 (16 per cent) had a malignancy in our series, an incidence which is greater than that previously reported. These cases incline us towards surgical excision whenever there is any recent or sudden enlargement of the gland.

Post-surgical hyponatraemia: the role of intravenous fluids and arginine vasopressin

T. H. THOMAS AND D. B. MORGAN*

SUMMARY

In 14 patients having undergone abdominal surgery, plasma sodium, urine volume and osmolality and the urinary excretion of arginine vasopressin (AVP), the antidiuretic hormone in man, were measured daily for 7 days. Each patient was given 3 l of intravenous fluids daily. In 8 patients the fluid was saline and in the other 6 it was dextrose-saline.

The plasma sodium did not change in the saline group whereas it fell in the dextrose–saline group during the day of operation and then remained low. On the day of operation the urinary AVP increased to very high levels in both groups of patients. On that day and during the postoperative period the AVP level and urine osmolality were much higher in the saline group than in the dextrose–saline group, which suggests that a loss or redistribution of extracellular fluid was not the cause of the high AVP. These results taken together suggest that it was the higher AVP level in the saline group that was required to keep the plasma sodium normal. On the other hand, the results suggest that in the dextrose–saline group, although the AVP was lower than in the saline group, it produced a urine osmolality greater than that necessary for balance so that the patients retained water and became hyponatraemic.

The fall in plasma sodium was small compared with that seen in patients with symptoms of water intoxication, but it may nevertheless have clinical effects and is best avoided. The results suggest that in these patients hyponatraemia can be avoided if saline rather than dextrose–saline is given on the day of operation.

PATIENTS after surgery are unable to excrete a water load as rapidly as before surgery and they become hyponatraemic if given too much dextrose solution intravenously (Le Quesne, 1954; Wynn, 1960). Dudley and his colleagues (1954) suggested that the failure to excrete the water was due to an excess of antidiuretic hormone, and increased levels of arginine vasopressin (AVP) in patients have been demonstrated by bioassay (Moran et al., 1964) and radioimmunoassay (Felsl et al., 1978; Haas and Glick, 1978). Patients after surgery have a diminished urinary excretion of sodium and they do not excrete all of a sodium load. This sodium retention has been attributed to a reduced plasma volume. Flear and Clark (1955) observed that sodium retention did not occur after trauma if the patients were given adequate blood transfusion. Irvin et al. (1972) reported that the urine sodium did not fall in patients after surgery if they were given balanced salt solution during as well as after the surgery. However, in the latter study the treatment did not prevent the excess ADH (as assessed by free water clearance), although it prevented the fall in plasma sodium seen in the patients given dextrose solution. This finding, which was not commented on by the authors, suggests that there is no simple relation between hyponatraemia and increased AVP.

The fall in plasma sodium which occurs in the majority of patients given dextrose or dextrose–saline after surgery is much smaller than that seen in patients with simple symptomatic water intoxication after surgery (Deutsch et al., 1966) or due to syntocinon (Morgan et al., 1977). However, there have been no studies designed to detect less obvious clinical effects in these patients showing small falls of plasma sodium, and until these investigations are made such falls in plasma sodium concentration are best avoided if possible. In order to obtain further information on the mechanism of this postoperative hyponatraemia we have studied the relations between plasma sodium, urine osmolality and AVP in patients having undergone surgery and given either saline or dextrose–saline intravenously.

Patients and methods

Fourteen patients were studied from the day before operation (day 0) until the seventh day after operation (day 7). The surgical procedures were cholecystectomy, vagotomy or hemicolectomy. The 8 patients in the saline group were given intravenously 3 l a day of saline containing 155 mmol/l of sodium chloride for 6 days beginning on the morning of the operation. The other 6 patients were given, for the same period, 3 l a day of dextrose–saline containing 278 mmol/l of glucose (4·3 per cent) and 30 mmol/l sodium chloride (0·18 per cent). A blood sample was taken each morning and 24-h urine collections were made for the 8 days of study (9.00 a.m. to 9.00 a.m.).

Plasma sodium was measured on a Vickers M300 multichannel analyser, urine osmolality was determined by freezing point depression on an Advance Osmometer and arginine vasopressin was measured in urine with a fully characterized radioimmunoassay (Thomas and Lee, 1976). The urinary excretion of AVP was expressed in terms of osmolar clearance (pg min^{-1} ml^{-1} osmolar clearance), and for the calculation of osmolar clearance, plasma osmolality was calculated as twice the plasma sodium concentration.

Results

Fig. 1 shows that the plasma sodium level was constant during the 8 days of the study in the saline group, whereas in the dextrose–saline group it fell by 5·9 mmol/l (range 3–11) after 1 day and by 7·1 mmol/l (range 5–11) after 2 days' treatment and then increased towards the preoperative value.

The maximum daily urine volume was similar in the two groups, but it was achieved on day 3 in the dextrose–saline group but not until day 6 in the saline group (*Fig.* 1). The osmolar excretion was two to three times greater in the saline group than in the dextrose–saline group. It was constant in the latter whereas in the saline group it increased to a maximum on day 5 (*Fig.* 1).

The urine osmolality was high throughout the study in the saline group whereas in the dextrose–saline

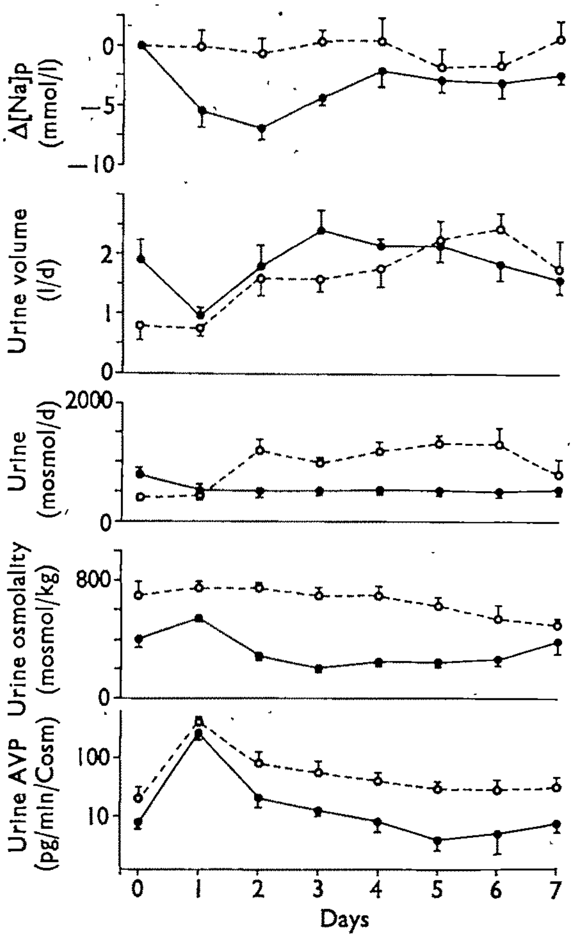

Fig. 1. The mean (±s.e.) values of plasma sodium concentration (as the difference from the value on day 0), urine volume, osmolar excretion, urine osmolality and urine arginine vasopressin (AVP) excretion on the day before operation (day 0), the day of operation (day 1) and for 6 days after operation (days 2–7) in 8 patients given intravenous saline (o——o) and 6 patients given intravenous dextrose–saline (●——●).

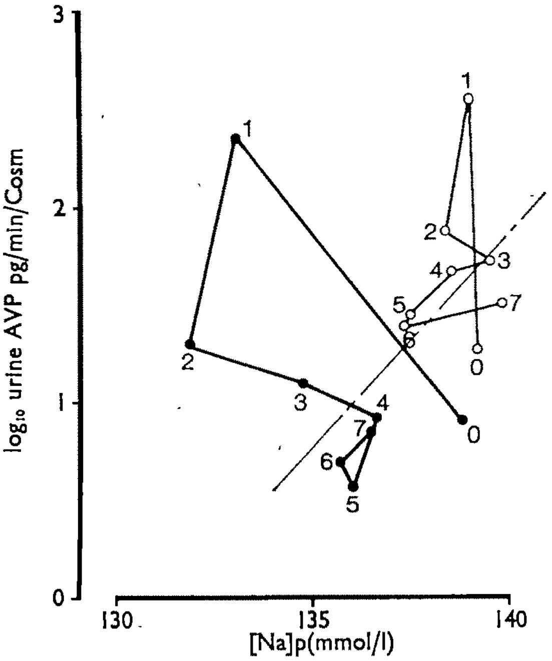

Fig. 2. The relationship between the mean values of plasma sodium concentration and urine arginine vasopressin (AVP) excretion on each day of study in 8 patients given intravenous saline (o——o) and 6 patients given intravenous dextrose–saline (●——●) postoperatively. The regression line is that observed in healthy subjects during water restriction (Thomas et al., 1978). Numbers against the points refer to the day of the study (day 1 was the day of operation).

group it was highest on the first day and then fell to a much lower value than that for the saline group (*Fig.* 1).

Fig. 1 shows the urine AVP results on a log scale. In both groups the urine AVP increased on the day of operation twentyfold compared with the preoperative values and then fell dramatically on the first postoperative day and more slowly on the subsequent days. However, throughout the postoperative period the AVP level in the saline group was four times that in the dextrose–saline group.

Fig. 2 shows that in the saline group, when all the results were taken together, the urine AVP was directly correlated with the plasma sodium concentration ($r = 0{\cdot}49$, $P < 0{\cdot}001$) and the mean daily values were close to the relationship observed in healthy persons deprived of water (Thomas et al., 1978). In contrast, in the dextrose–saline group, there was overall a negative correlation between the urine AVP level and the plasma sodium concentration ($r = 0{\cdot}40$, $P < 0{\cdot}05$). This negative correlation arose because the mean values for days 1, 2 and 3 were outside the relationship observed in healthy persons, with a much higher urine osmolality than would be expected for the plasma sodium.

Discussion

There has been no previous comparison of the effects of saline and dextrose–saline on plasma sodium concentration and antidiuretic hormone in patients after surgery. In the present study, on the day of operation the AVP increased in both groups of patients to levels which were much higher than those achieved by simple water depletion and much higher than would be expected from the plasma sodium concentration. On subsequent days the urine AVP was higher in the saline group, whose plasma sodium remained normal, than in the dextrose–saline group whose plasma sodium fell. These findings indicate that a suppression of AVP secretion was not the mechanism that prevented the fall in plasma sodium concentration in the saline group. They further suggest that a reduction in plasma volume or total extracellular fluid volume, which would have been diminished or corrected by the saline, was unlikely to be the cause of the increased AVP in either group. The initial increase in the AVP in both groups was therefore, presumably, a part of the stress response to the surgical operation (Moran et al., 1964).

In the saline group the plasma sodium concentration did not change during the 7 days of the study, and it must therefore have been the urine osmolality that was required to keep the plasma sodium normal. This finding suggests that in the saline group the AVP secretion was under osmotic control. In the dextrose–saline group the urine osmolality decreased after the first postoperative day to much lower values than in the saline group. Nevertheless, in the dextrose–saline group the urine osmolality on the first postoperative day must have been higher than was required for balance because the plasma sodium fell. The AVP in the dextrose–saline group must therefore have remained too high for the plasma osmolality so that the plasma AVP determined the plasma sodium rather than the other way round. These results therefore suggest that in the dextrose–saline group on the day of operation, the AVP was maintained by a non-osmolar stimulus at a level which produced an inappropriately high urine osmolality, water retention and a fall in plasma sodium due to a dilution of the extracellular fluid. Whereas the fall in plasma sodium may be due to simple dilution in patients such as ours, having undergone uncomplicated surgery (Wynn and Houghton, 1957; Singh and Flear, 1968), in some patients with complicated surgery part of the fall may be due to increased cellular permeability (Flear, 1970; Tindall and Clark, 1976).

Our general conclusion is that the stress of surgery maintained the AVP at a minimum level below which it could not be suppressed and that this minimum level determined the minimum obtainable urine osmolality. If a treatment was given that required for water balance a lower urine osmolality than this minimum, then water would be retained and the plasma sodium would fall. However, apart from this restriction, the osmolality control system is intact and urine osmolalities above this minimum could be produced as needed to maintain a normal plasma sodium.

We have calculated for our patients the minium requirements to maintain water balance and prevent the fall in plasma sodium. The calculation assumes that as the dextrose-treated patients were hyponatraemic they had no osmotic drive to AVP secretion. The fall in plasma sodium occurred on day 1 and calculations suggest that in order to prevent this fall, if 3 l of fluid were given, the fluid would have to contain at least 130 mmol/l of sodium chloride. Further calculations suggest that on days 2, 3 and 4, 3 l of only 20 mmol/l of sodium chloride could be given without a fall in plasma sodium. This was the treatment given to the dextrose group on those days and the plasma sodium did not fall. However, since this treatment was the requirement for balance, it did not allow the plasma sodium to increase from the low value it had already fallen to on day 1. The results suggest that in patients such as ours the fall in plasma sodium could be prevented by giving saline on day 1 and dextrose–saline on the subsequent days. In other groups of patients the AVP may remain high for longer than 1 day and dextrose–saline would then have to be avoided until the AVP fell to lower values.

The usual approach to fluid therapy after operation seems to be an attempt to ensure that the patient excretes the same volume of urine and amount of sodium as before operation. We suggest that in terms of water the choice of treatment should be based on what the patient can excrete without being overloaded.

The two groups of patients received the same volume of intravenous fluid and their urine volumes were similar, so that they retained similar volumes of water. Both groups not only had an increase in AVP due to the stress response, but would also have retained some of a sodium load (Moran et al., 1964). The patients in the dextrose–saline group became hyponatraemic because they were given water without sodium. The saline group retained sodium with water and the plasma sodium did not change. This sodium retention may well be due to a reduced plasma volume (Irvin et al., 1972; Enquist et al., 1978) but, as we have emphasized, a low plasma volume is unlikely to be the explanation of the increased AVP which causes the hyponatraemia in the patients given dextrose–saline.

Acknowledgements

We thank Mr Graham Hill for permission to study his patients, Dr R. Swaminathan and Dr A. Bradley, who organized the study and collected the samples, Mr David Halliday and Mr Chris Hood, who made the AVP measurements, and the nursing staff on Wards 27 and 28 at the Leeds General Infirmary for their cooperation and help.

Effect of epidural analgesia on metabolic profiles during and after surgery

H. KEHLET, M. R. BRANDT, A. PRANGE HANSEN AND
K. G. M. M. ALBERTI*

SUMMARY

Blood concentrations of glucose, lactate, alanine, free fatty acids, glycerol and 3-hydroxybutyrate were measured during 24 h in 12 females undergoing elective hysterectomy under either general anaesthesia or epidural analgesia extending from T4 to S5. The results showed that the peroperative and immediate postoperative metabolic profiles in the group receiving general anaesthesia reflected substrate mobilization (increased glucose, lactate, 3-hydroxybutyrate), and that epidural analgesia blocked these changes, probably mediated through an inhibited adrenaline response to surgery. Peroperative values of free fatty acids and glycerol were significantly lowered by epidural analgesia, indicating inhibition of lipolysis. Alanine decreased similarly in both groups. In the later postoperative period metabolic profiles were similar in the two groups, indicating that the influence of fasting may override the effect of the relatively minor trauma.

BLOCKADE of afferent neurogenic stimuli from the surgical area by epidural analgesia inhibits various parameters of the endocrine response to surgery, such as cortisol (Engquist et al., 1977), growth hormone (Brandt, Kehlet, Binder et al., 1976) and aldosterone and renin (Brandt, Ølgaard et al., 1979), while postoperative changes in thyroid hormones (Brandt, Kehlet, Skovsted et al., 1976) are unaffected. Insulin secretion is probably slightly inhibited (Brandt, Kehlet and Binder, 1976; Brandt et al., 1977). Although the overall effect of epidural analgesia results in an improved postoperative nitrogen balance (Brandt, Fernandes et al., 1978), the influence on per- and postoperative metabolic profiles is unknown. In this study we describe the influence of epidural analgesia on postoperative changes in blood glucose, lactate, alanine, glycerol, free fatty acids (FFA) and 3-hydroxybutyrate.

Patients and methods

Twelve otherwise healthy and premenopausal women undergoing elective abdominal hysterectomy for menorrhagia or cancer of the cervix in stage 0–1 were studied during operation and for 24 h afterwards. Ages ranged from 27 to 47 years (average 36 years in the epidural group, and 38 years in the control group). All patients had a normal nutritional status (average weight 59·3±2·9 (s.e. mean) kg in the epidural group and 53·8±1·6 kg in the control group, $P>0·05$). All patients had a normal preoperative dietary intake, but they received no calories (oral or intravenous) from 10 h before to 24 h after skin incision. None of the patients suffered from cardiovascular, renal, hepatic or hormonal diseases nor received any medications, including hormonal contraceptives. Informed consent to participate in the study was obtained from all patients.

Six patients had general anaesthesia with thiopentone–halothane–nitrous oxide/oxygen, and 6 patients had epidural analgesia without general anaesthesia, using 0·5 per cent bupivacaine (Marcaine) without adrenaline. Analgesia, which extended from T4 to S5, was effective before skin incision and was controlled continuously during the following 24 h, constantly keeping the patients pain-free. Both groups were premedicated with pethidine 1 mg/kg, promethazine 12·5–25 mg and atropine 0·5 mg. A detailed description of the technique of general anaesthesia and epidural analgesia is reported elsewhere (Engquist et al., 1977). Operation started between 9 and 11 a.m. and required between 60 and 120 min (average 88 min in the epidural group and 93 min in the control group, $P>0·05$).

Patients operated under general anaesthesia received postoperative analgesia, 50 mg of pethidine every fourth to sixth hour, while patients operated under epidural analgesia were pain-free and had no other postoperative analgesia. During the first 24 postoperative hours, all patients received only isotonic saline intravenously and tap water orally. Twelve blood samples were drawn from a central venous catheter: 15 and 5 min before induction of anaesthesia or epidural analgesia, at skin incision and ½, 1, 2, 3, 4, 6, 9, 14 and 24 h after skin incision. Blood for metabolic estimations was deproteinized immediately after withdrawal by addition of 5 per cent (v/v) perchloric acid. Samples were centrifuged and stored at −21 °C within 20 min after sampling. Blood, blood substitutes or sympathomimetics were not given. Blood loss was similar (about 220 ml) in both groups. No patient had any postoperative complication.

Glucose was measured by a routine glucose oxidase method and lactate, alanine, glycerol and 3-hydroxybutyrate by enzymatic automated, fluorometric techniques (Lloyd et al., 1978) and FFA by a radioactive cobalt method (Ho and Meng, 1969). Cortisol was estimated by a protein-binding technique (Kehlet et al., 1974) and insulin (Heding, 1972) and growth hormone (Ørskov et al., 1968) by radioimmunoassays.

Student's *t* test for paired and unpaired data was used to test statistical significance. $P<0·05$ was considered significant.

Results

The results are summarized in *Figs.* 1–6.

Glucose

Blood glucose (*Fig.* 1) increased ($P<0·05$) immediately after skin incision in the control group and remained elevated ($P<0·05$) during the following 14 h. Epidural analgesia blocked the hyperglycaemic response to surgery throughout the study. Differences between groups were significant from 1 to 4 h and 9 h after skin incision.

Alanine

Blood alanine (*Fig.* 2) decreased ($P<0·05$) after surgery in both groups and remained lower than the preoperative value throughout the study. Except for lower values ($P<0·05$) in the epidural group 14 h after skin incision, there were no differences between the groups.

Lactate

Blood lactate (*Fig.* 3) was already increased ($P<0·05$) in the general anaesthesia group at the time of skin

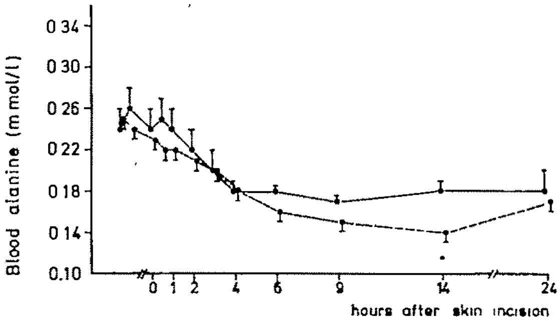

Fig. 2. Effect of epidural analgesia on alanine in blood during and after surgery. Symbols and numbers of cases as *Fig. 1*; values mean±s.e. mean.

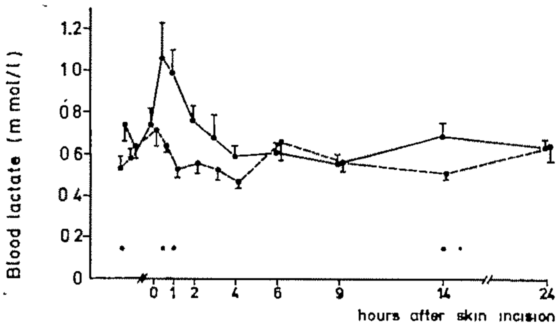

Fig. 3. Effect of epidural analgesia on lactate in blood during and after surgery. Symbols and numbers of cases as *Fig. 1*; values mean±s.e. mean.

incision and remained elevated during the following 3 h. In contrast, no changes in blood lactate were observed in the epidural group. Values were higher ($P<0{\cdot}05$) in the first preoperative sample in the epidural group, while 30 min and 1 and 14 h after skin incision values were higher ($P<0{\cdot}05$) in patients receiving general anaesthesia.

Glycerol

Blood glycerol (*Fig.* 4) showed no change in the general anaesthesia group while values decreased 1 h after skin incision in the epidural group. A difference ($P<0{\cdot}05$) between groups could only be detected 1 h after skin incision.

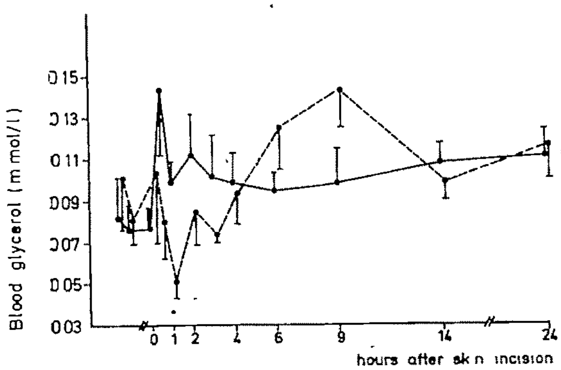

Fig. 4. Effect of epidural analgesia on glycerol in blood during and after surgery. Symbols and numbers of cases as *Fig.* 1; values mean±s.e. mean.

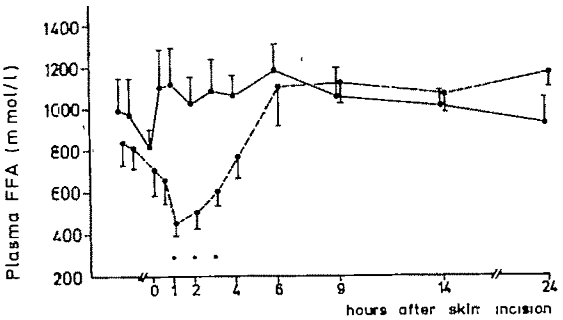

Fig. 5. Effect of epidural analgesia on free fatty acids (FFA) in plasma during and after surgery. Symbols and numbers of cases as *Fig.* 1; values mean±s.e. mean.

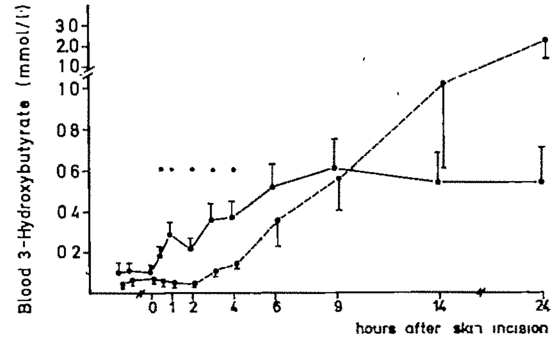

Fig. 6. Effect of epidural analgesia on 3-hydroxybutyrate in blood during and after surgery. Symbols and numbers of cases as *Fig.* 1; values mean±s.e. mean.

Free fatty acids (FFA)

Plasma FFA (*Fig.* 5) showed no significant change in the general anaesthesia group, while values decreased ($P<0{\cdot}05$) 1 h after skin incision in the epidural group. Mean values were lower ($P<0{\cdot}05$) 1–3 h after skin incision in the epidural group compared with the general anaesthesia group.

3-Hydroxybutyrate

Blood 3-hydroxybutyrate (*Fig.* 6) concentrations increased ($P<0{\cdot}05$) 30 min after skin incision in the general anaesthesia group and remained elevated throughout the study. In contrast, 3-hydroxybutyrate in the epidural group showed no changes until 4 h after skin incision, after which increased ($P<0.05$) values were observed. Differences between groups were significant from 30 min to 4 h after skin incision.

Cortisol, insulin and growth hormone

Plasma cortisol increased ($P<0.05$) immediately after skin incision in the general anaesthesia group from 246 ± 41 nmol/l (mean ± s.e. mean) before skin incision to a maximum of 1090 ± 57 nmol/l 3 and 6 h later and remained elevated ($P<0.05$) throughout the study compared with the preoperative value. Epidural analgesia blocked the cortisol response to surgery, the average concentrations being about 400–500 nmol/l throughout the study. Differences between groups were significant from 30 min to 9 h after skin incision. Plasma insulin decreased slightly ($P<0.05$) in the epidural group from 80 ± 20 pmol/l (mean ± s.e. mean) to 50 ± 20 pmol/l from the time of skin incision and throughout the study. In the general anaesthesia group values were not significantly changed from the preanaesthetic value (50 ± 20 pmol/l) except for a decrease 30 min after skin incision (20 ± 5 pmol/l). Differences between groups were not significant.

Plasma growth hormone increased ($P<0.05$) from 3·2 ± 1·4 ng/l (mean ± s.e. mean) to 17·4 ± 4·3 ng/l 30 min after skin incision in the general anaesthesia group, while no peroperative changes were observed in the epidural group. Differences between groups were significant 30 min and 1 h after skin incision. Postoperatively, patients under epidural analgesia showed intermittently very high values and no differences between groups were observed.

Discussion

The influence of neurogenic blockade by epidural analgesia on the endocrine response to surgery has recently been reviewed (Kehlet, 1978). It appears that epidural analgesia inhibits the normal per- and postoperative increase in cortisol, growth hormone, aldosterone, renin and adrenaline, the latter shown indirectly through an inhibited cyclic AMP response. Per- and postoperative changes in thyroxine and triiodothyronine as well as glucagon are not influenced by epidural analgesia, while insulin is slightly inhibited. This study considers initial per- and postoperative changes in metabolic profiles and their possible modifications by epidural analgesia.

Glucose

Our results confirm that the normal hyperglycaemic response to surgery is abolished by epidural analgesia (Bromage et al., 1971; Engquist et al., 1977). This effect is probably mediated through the inhibited adrenaline response or blockade of sympathetic pathways to the liver as discussed previously (Brandt, Kehlet, Binder et al., 1976).

Alanine

Alanine decreased rapidly after surgery, but similarly during general anaesthesia and epidural analgesia. The underlying mechanism behind the postoperative decrease in blood alanine, also demonstrated by others (Schønheyder et al., 1974; Wedge et al., 1976; Foster et al., 1979), is unknown. However, fasting may be a contributory factor, since blood alanine decreases during fasting due to an increased splanchnic uptake (Felig et al., 1969) despite a concomitantly increased release from muscle (Pozetsky et al., 1976). In severe trauma, i.e. burns, elevated blood levels of alanine have been observed (Batstone et al., 1976) and thought to be secondary to increased cortisol levels since glucocorticoids increase blood alanine (Wise et al., 1973). However, during elective surgery other mechanisms may regulate alanine homeostasis since alanine levels were decreasing similarly during general anaesthesia and epidural analgesia despite a pronounced difference in cortisol levels.

Lactate

Blood lactate increased during general anaesthesia and surgery, as found by others (Greene, 1961), but values were normal postoperatively, which is again in agreement with others (Rowlands et al., 1977; Foster et al., 1979). That the peroperative increase in lactate is partly mediated via the anaesthetic agent itself (Greene, 1961) is confirmed by our results showing a rise in lactate at the time of skin incision. However, the surgically induced adrenaline release (Halter et al., 1977; Nistrup Madsen et al., 1978) may also result in a rise in blood lactate (Christensen et al., 1975). The constant lactate levels during epidural analgesia are in accordance with the blocked adrenaline response and the omission of general anaesthesia.

Glycerol and FFA

The surgical procedure may initiate an increase in blood glycerol and FFA (Hallberg and Orö, 1965), probably as a result of increased lipolysis due to catecholamine release. Our results showed only an insignificant increase in glycerol and FFA after skin incision in the general anaesthesia group, but during epidural analgesia and surgery levels of both metabolites decreased rapidly in accordance with the inhibited catecholamine secretion. Similar observations have been made during spinal anaesthesia (Hallberg and Orö, 1965). In contrast, Oyama and Matsuki (1970) found spinal anaesthesia to have no influence on plasma FFA, but their patients had varying and very minor surgery. Furthermore, postoperative determinations were made, by which time analgesia was ineffective.

3-Hydroxybutyrate

Surgery performed under general anaesthesia elicited an increase in 3-hydroxybutyrate immediately after skin incision, probably as a result of release of adrenaline, which is known to increase blood 3-hydroxybutyrate (Christensen et al., 1975). However, growth hormone and cortisol may also contribute to the ketogenic response during the postoperative phase with relative insulin deficiency (Alberti et al., 1978). In accordance with the blocked adrenaline response, epidural analgesia inhibited the surgically induced increase in 3-hydroxybutyrate, but levels began to increase 4 h after skin incision, probably due to the influence of fasting (Foster et al., 1979).

In summary, epidural analgesia blocked the changes in blood metabolic profiles induced by the surgical procedure, predominantly mediated through an inhibited adrenaline response to surgery. Postoperative metabolic profiles were mainly unaffected by epidural analgesia, except for the lack of hyperglycaemia, probably reflecting that the influence of starvation may override the metabolic response to such relatively minor trauma as hysterectomy. The inhibited cortisol and growth hormone response to surgery during epidural analgesia probably did not have any major influence on per- and early postoperative changes in the intermediary metabolic profiles in blood, since these hormones have no major acute effects on glucose, FFA and 3-hydroxybutyrate (Marco et al., 1973; Fineberg and Merimee, 1974; Schade et al., 1977). Neither did the slight decrease in insulin during epidural analgesia seem to be of importance, except as a contributory factor to postoperative ketogenesis. Despite the apparently short term effects of epidural analgesia on the surgically induced changes in the various endocrine–metabolic parameters in blood found in this study, a longer lasting effect on metabolic balance has been demonstrated by means of an improved 5-day postoperative nitrogen balance (Brandt, Fernandes et al., 1978). However, since metabolic and endocrine profiles in this latter study were only measured during the first 24 h, the explanation of the sustained effect of epidural analgesia on postoperative metabolism is unclear.

How Seward put it all together...

You can't set a machine to make a Balfour's Abdominal Retractor. It needs the skilled work of an experienced craftsman, using his hands. And he has to work within exceptionally fine tolerances to ensure that each part will fit perfectly when he puts it all together.

Not every instrument supplier has the resources for this type of work. But at Seward we do – our own workshops and a team of expert craftsmen.

It can be a slow process making instruments by hand. Some things just can't be rushed. But we don't keep you waiting, because we hold ample stocks of all the instruments in our range. That's another very important part of Seward service – another way we put it all together.

Seward – the fast word in quality

Postprandial serum gastrin levels in patients with combined hypergastrinaemia and hyperchlorhydria

C. B. H. LAMERS AND J. H. M. VAN TONGEREN*

SUMMARY

We have determined the serum gastrin response to a standard test meal in 13 unoperated patients with combined fasting hypergastrinaemia (more than 150 ng/l) and basal hypersecretion of gastric acid (BAO more than 10 mmol/h). In 10 of 11 patients with proved or presumptive Zollinger–Ellison syndrome the peak postprandial rise in serum gastrin concentration was less than 50 per cent of basal value. The integrated gastrin response to feeding ranged from −71·9 to 211·8 μg/l× 150 min. In 2 patients with proved hypergastrinaemia of antral origin, however, serum gastrin rose to 223 per cent and 255 per cent respectively of basal value after ingestion of the meal. The integrated postprandial serum gastrin responses in these patients were 66·8 and 22·0 μg/l×150 min. Two patients with Zollinger–Ellison syndrome and total gastrectomy showed peak serum gastrin levels after feeding of 174 and 255 per cent of basal concentration. The integrated postprandial gastrin secretions were 365 and 366 μg/l×150 min respectively.

It is concluded that the serum gastrin response to feeding, when expressed as percentage change, may be helpful in the differential diagnosis of unoperated patients with fasting hypergastrinaemia and basal gastric acid hypersecretion.

INGESTION of food is a physiological stimulus for the release of gastrin from the mucosa of the antrum and duodenum (Berson and Yalow, 1972). The postprandial rise in serum gastrin is therefore considered to be an indirect test of the gastrin-cell function of the gastroduodenal mucosa.

In patients with combined fasting hypergastrinaemia and basal hyperchlorhydria, elevated serum gastrin concentrations may arise either from the antral mucosa (primary hypergastrinaemia of antral origin) or from extra-gastric sources (Zollinger–Ellison syndrome) (Berson and Yalow, 1972; Isenberg et al., 1973; Walsh and Grossman, 1975). It has been suggested that the serum gastrin response to feeding is helpful in the differentiation between these two sources of hypergastrinaemia (Berson and Yalow, 1972). This differentiation is based upon the supposition that feeding stimulates gastrin release from the antroduodenal mucosa but not from gastrin-producing tumours (Isenberg et al., 1973). Recent studies, however, have shown that some of the patients with Zollinger–Ellison syndrome show large postprandial rises in serum gastrin (Creutzfeldt et al., 1975; Thompson et al., 1975). Unfortunately, many patients in those studies had undergone previous gastric or pancreatic surgery.

In view of conflicting data on postprandial serum gastrin levels in the limited reported number of unoperated patients with combined fasting hypergastrinaemia and basal gastric acid hypersecretion (Berson and Yalow, 1972; Creutzfeldt et al., 1975; Thompson et al., 1975), we report on the serum gastrin response to feeding in 13 such patients. Three had histologically proved Zollinger–Ellison syndrome, 8 presumptive Zollinger–Ellison syndrome and 2 hypergastrinaemia of antral origin. Furthermore, 2 of the patients with Zollinger–Ellison syndrome were studied after total gastrectomy.

Patients and methods

All patients included in this study had fasting hypergastrinaemia (a level of more than 150 ng/l) and basal hypersecretion of gastric acid (BAO more than 10 mmol/h). Except for the 2 patients with total gastrectomy, none had undergone previous gastric or pancreatic surgery. Three patients in whom the Zollinger–Ellison syndrome was histologically proved at a later date had fasting serum gastrin levels ranging from 1240 to 5800 ng/l and a BAO of between 17·0 and 57·5 mmol/h. The diagnosis of presumptive Zollinger–Ellison syndrome was based upon a rise in serum gastrin of more than 50 per cent of basal value within 30 s of intravenous administration of 1 unit secretin (from the Gastrointestinal Hormone Research Laboratory, Karolinska Institute, Stockholm), per kilogramme body weight (Lamers et al., 1977). In these 8 patients serum gastrin ranged from 170 to 780 ng/l with a BAO of between 15·1 and 67 mmol/h. The 2 patients with primary hypergastrinaemia of antral origin had serum gastrin concentrations of 160 and 415 ng/l and BAOs of 11·3 and 11·0 mmol/h respectively. Both serum gastrin (36 and 67 ng/l) and BAO (0 and 0·7 mmol/h) returned to normal after antrectomy. The 2 Zollinger–Ellison syndrome patients studied after total gastrectomy had serum gastrin concentrations of 3280 and 5130 ng/l at the time of study.

After an overnight fast the subjects ingested a standard test meal within 15 min. This meal consisted of one slice of bread, 50 g cheese, one boiled egg and 200 ml milk, corresponding to 30 g protein, 20 g fat and 25 g carbohydrate. Before and 15, 30, 45, 60, 90, 120 and 150 min after the start of the meal blood was drawn for measurement of gastrin.

Serum gastrin levels were measured by radioimmunoassay using a rabbit antiserum (Lamers et al., 1977). The antiserum was raised against synthetic human gastrin I containing amino acid residues 2–17, conjugated to bovine albumin (Rehfeld et al., 1972). It had an almost equimolar potency to bind gastrin-17 and gastrin-34 (Rehfeld et al., 1975). Serum gastrin levels in 100 normal controls were 66±18 ng/l (mean±s.d.). The integrated serum gastrin response to feeding was determined by calculating the area under the curve after subtraction of the basal gastrin concentration. Ingestion of the standard test meal in 12 normal subjects induced an increase in serum gastrin from 52±12 ng/l (mean±s.d.) to a peak of 97±33 ng/l at 60 min. The integrated gastrin response to feeding in these 12 normal subjects was 5·2±2·9 μg/l × 150 min (Lamers, 1977).

Statistical analysis was performed by Wilcoxon's two-sample test.

Results

Two of the 3 patients with histologically proved Zollinger–Ellison syndrome had a slight postprandial rise in serum gastrin, while the other patient showed a small decrease in circulating gastrin levels (*Fig.* 1). In none of the patients did the postprandial increase in serum gastrin exceed 50 per cent of the basal value. The integrated postprandial gastrin secretion was −71·9, 24·7 and 211·8 μg/l × 150 min respectively.

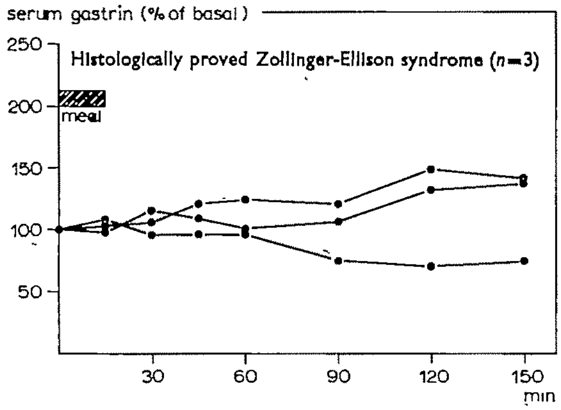

Fig. 1. Postprandial serum gastrin levels in patients with histologically proved Zollinger–Ellison syndrome.

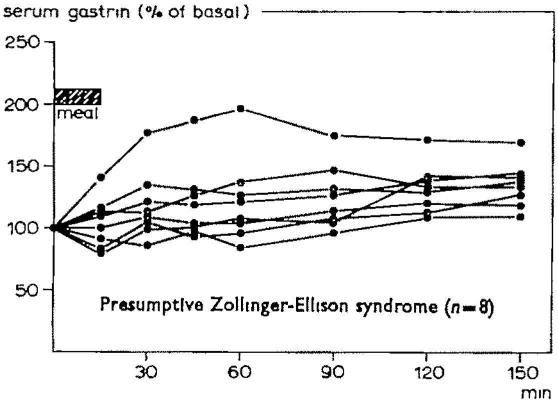

Fig 2. Postprandial serum gastrin levels in patients with presumptive Zollinger–Ellison syndrome.

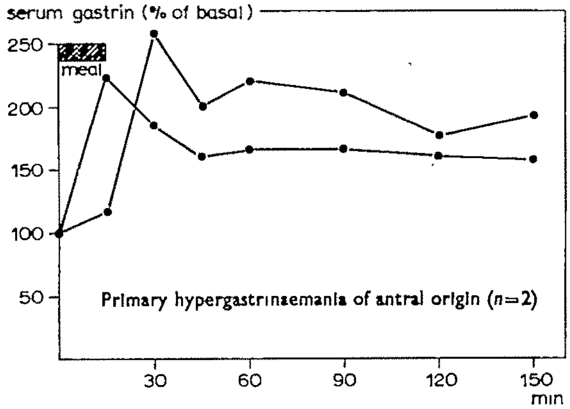

Fig. 3. Postprandial serum gastrin levels in patients with primary hypergastrinaemia of antral origin.

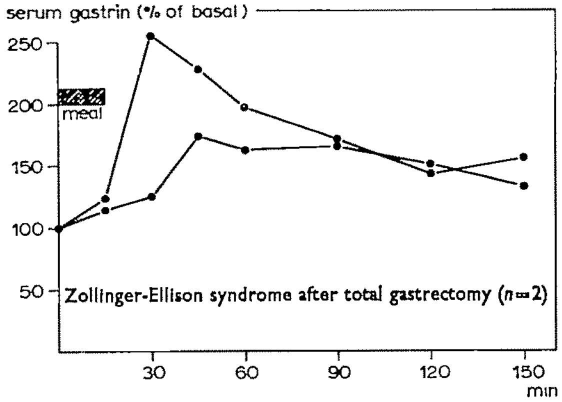

Fig. 4. Postprandial serum gastrin levels in patients with Zollinger–Ellison syndrome having undergone total gastrectomy.

Seven of the 8 patients with presumptive Zollinger–Ellison syndrome had slight postprandial increases in serum gastrin of less than 50 per cent of the basal value (*Fig.* 2). In one patient, however, serum gastrin almost doubled after ingestion of the test meal. In this group of patients serum gastrin concentrations at 90, 120 and 150 min were significantly ($P<0{\cdot}05$) elevated above basal level. The integrated gastrin response to feeding ranged from 3·9 to 81·3 μg/l × 150 min with a median of 9·8 μg/l × 150 min.

Two patients with hypergastrinaemia of antral origin showed a rise in serum gastrin of more than 120 per cent of basal value (*Fig.* 3). The integrated postprandial gastrin responses in these patients were 22·0 and 66·8 μg/l × 150 min respectively.

The 2 patients with Zollinger–Ellison syndrome who had undergone total gastrectomy showed marked postprandial increases in serum gastrin to 174 and 255 per cent of basal value respectively (*Fig.* 4). The integrated gastrin responses to feeding were 365 and 366 μg/l × 150 min.

Discussion

The present study shows that postprandial rises in serum gastrin in 10 of 11 patients with proved or presumptive Zollinger–Ellison syndrome were less than 50 per cent of basal value. On the other hand, the two patients with proved hypergastrinaemia of antral origin had postprandial increases in serum gastrin of more than 120 per cent. The possibility that the patient with presumptive Zollinger–Ellison syndrome and a marked postprandial rise in serum gastrin was in fact suffering from hypergastrinaemia of antral origin was excluded by the finding of persistent hypergastrinaemia after total gastrectomy. Although the number of patients with hypergastrinaemia of antral origin in the present study is small, the results are supported by data on postprandial serum gastrin levels in patients with presumed or proved hypergastrinaemia of antral origin studied by others (Berson and Yalow, 1972; DiMagno and Go, 1974; Straus and Yalow, 1975). It can therefore be concluded that the finding of marked postprandial increases in serum gastrin should raise the suspicion of hypergastrinaemia of antral origin, although the Zollinger–Ellison syndrome cannot be excluded with certainty. Furthermore, the serum gastrin response to secretin may also be helpful in the differential diagnosis of these patients. Since not every case of Zollinger–Ellison syndrome shows a marked gastrin response to intravenous secretin (Lamers et al., 1977), both the meal and the secretin stimulation test should be done to obtain optimal diagnostic information.

The integrated gastrin response to feeding in some patients with Zollinger–Ellison syndrome was much greater than in normal controls. We cannot, therefore, exclude the possibility that some of the gastrin released after feeding in such patients originates from gastrinoma tissue. This suggestion is supported by the finding of large postprandial increases in serum gastrin in 2 cases with Zollinger–Ellison syndrome after total gastrectomy. This marked gastrin response to feeding has been described previously in a larger group of totally gastrectomized patients with the syndrome (Thompson et al., 1975). These authors suggested that the postprandial release of gastrin in such patients was mediated by a humoral factor. Passaro and Walsh (1977) showed that perfusion of the proximal duodenum with acid, peptone or alcohol in totally gastrectomized patients with Zollinger–Ellison syndrome led to marked increases in serum gastrin. These authors therefore postulated that a duodenal agent, other than secretin, causes the release of gastrin from gastrinoma.

It can be concluded that measurement of postprandial serum gastrin has some, although limited, significance in the differential diagnosis of unoperated patients with fasting hypergastrinaemia and basal hypersecretion of gastric acid. Obviously, studies in larger groups of patients are needed to elucidate further the discriminative potency of meal stimulation tests in such patients.

Prolonged post-vagotomy gastric atony treated by oxytocin

M. HASHMONAI, S. TOREM, S. ARGOV, A. BARZILAI AND A. SCHRAMEK*

SUMMARY

Persistent and complete post-vagotomy gastric atony was treated in 3 patients by intravenous infusion of oxytocin. Despite failure of both conventional treatment with gastric aspiration and intravenous fluids or jejunal feeding, as well as the reported trials with bethanechol chloride and metoclopramide, these patients promptly responded to oxytocin. It appears that the latter may represent a solution to this uncommon but recalcitrant complication of peptic ulcer surgery.

SEVERE gastric atony is an unusual but well-recognized complication of vagotomy with a drainage procedure. It is due to a motor dysfunction of the stomach resulting in absence of peristalsis. Thus, although an adequate anatomic outlet exists, stomach emptying does not take place. Despite treatment by gastric aspiration and parenteral or jejunal feeding, this condition may persist for a long period, even months.

The purpose of this study is to present a new pharmacological approach to this problem—the use of intravenous oxytocin.

Patients and methods

Three young male patients were studied. Each had a duodenal ulcer complicated by pyloric stenosis. They had been suffering from epigastric pain for 7–16 years. Two of them had bled from their ulcers. All three had been vomiting, one for the past 3 years, one for 1½ years and the third for 5 months. Upper gastrointestinal barium studies performed before surgery showed a duodenal ulcer with a severely deformed and narrowed pyloric canal with slow emptying of a moderately (in the first and second cases) and severely (in the third case) dilated stomach. In all, a truncal vagotomy and Jaboulay gastroduodenostomy were performed. Two of the patients had an apparently uneventful recovery and were discharged on the eighth postoperative day. One week later both were readmitted because of epigastric fullness and vomiting. The third patient developed the same complaints in the immediate post-postoperative period.

Barium meal examinations showed a grossly dilated, persistently aperistaltic stomach in each case. Very limited gastric emptying was demonstrated in certain postures only by the gravitational flow of barium through the anastomosis, which was wide and patent. Plain abdominal X-rays, performed 24 h later, showed that most of the barium was still in the stomach. In 2 cases, patency of the anastomosis was confirmed on gastroscopy.

The first patient was treated by persistent nasogastric aspiration and total parenteral alimentation. The other 2 patients were treated by aspiration via a gastrostomy and by tube jejunal feeding. However, repeated barium fluoroscopic examinations showed that the stomach had not recovered its motility and no significant reduction in the amount of gastric aspiration occurred (*Fig.* 1). An attempt to treat the first patient with metoclopramide and bethanechol chloride 3 months after his operation failed. After the gastric atony had persisted for 4 months in the first case and for 2 months in the other two, oxytocin treatment was started. An intravenous infusion of 5–20 units of oxytocin in 500 ml of normal saline was administered every 4 h for 3 days. Each patient was submitted to a fluoroscopic barium examination immediately before the onset of this treatment. The stomach was found to be, as in all previous examinations, completely atonic, lacking any peristaltic movement and rather distended despite the persistent gastric aspiration. Twenty to thirty minutes after onset of the oxytocin infusion, some contractions of the stomach appeared. Repeated barium meals performed after 3 days of treatment showed effective gastric contractions in one case, partially effective contractions in another and only some reversed peristaltic waves in the third patient. In the latter case, oxytocin was continued for 3 additional days, after which effective peristalsis of the stomach was achieved. A concomitant drastic decrease in the amount of gastric aspirate was also observed (*Fig.* 1). After the oxytocin was discontinued, the gastric aspiration was maintained for another day and, as no rise in the amount was recorded, the tubes were taken out and the patients were placed on a normal diet. A barium meal performed 3 weeks later showed effective contractions of the stomach with complete emptying within 90–120 min.

The side effects of this treatment were colicky abdominal pain, mainly in the epigastrium, and some bouts of diarrhoea. These were overcome by reducing the dosage of oxytocin.

Discussion

Despite the introduction of selective and highly selective vagotomy, truncal vagotomy with a drainage procedure is still the commonest surgical treatment for peptic ulcer. Gastric motility is always disturbed after any type of vagotomy, but particularly after the truncal section of the vagi (Sheiner and Catchpole, 1976). Pyloroplasty slightly slows the rate of gastric emptying. When a vagotomy is performed, the gastric motility is considerably slower than normal and when a pyloroplasty is added, although much enhanced, gastric emptying is still slower than normal (Edwards and Rowlands, 1968). This disturbance is caused by a complex alteration of gastric motor function. In the normal stomach, the major muscular activity promoting emptying is phasic synchronized peristalsis. The major muscular activity promoting gastric emptying after vagotomy is tonic pressure change plus poorly synchronized abbreviated phasic activity (Nelsen et al., 1967). Yet, in the majority of patients, no significant clinical symptoms persist. This is probably due to the partial restoration of gastric motility through a peripheral motor mechanism controlled by the Auerbach's plexus (Dragstedt et al., 1947). The cause for the complete gastric atony that is occasionally observed following vagotomy is still obscure (Donovan and Alexander-Williams, 1976), but it may be associated with previous gastric distension due to pyloric stenosis, as reported in the majority of the cases in the literature (Bergin and Jordan, 1959; Vasconez et al., 1970; Sheiner and Catchpole, 1976). Indeed, gastric atony was observed in 5 per cent of patients following vagotomy with a drainage procedure for non-obstructing duodenal ulcer and in 27 per cent of cases having a similar procedure for pyloric obstruction (Kraft et al., 1964). It seems that this is a cumulative result of previous chronic gastric distension plus autonomic gastric motor denervation (Kraft et al., 1964). All three of our cases had pyloric stenosis complicating their peptic ulcer.

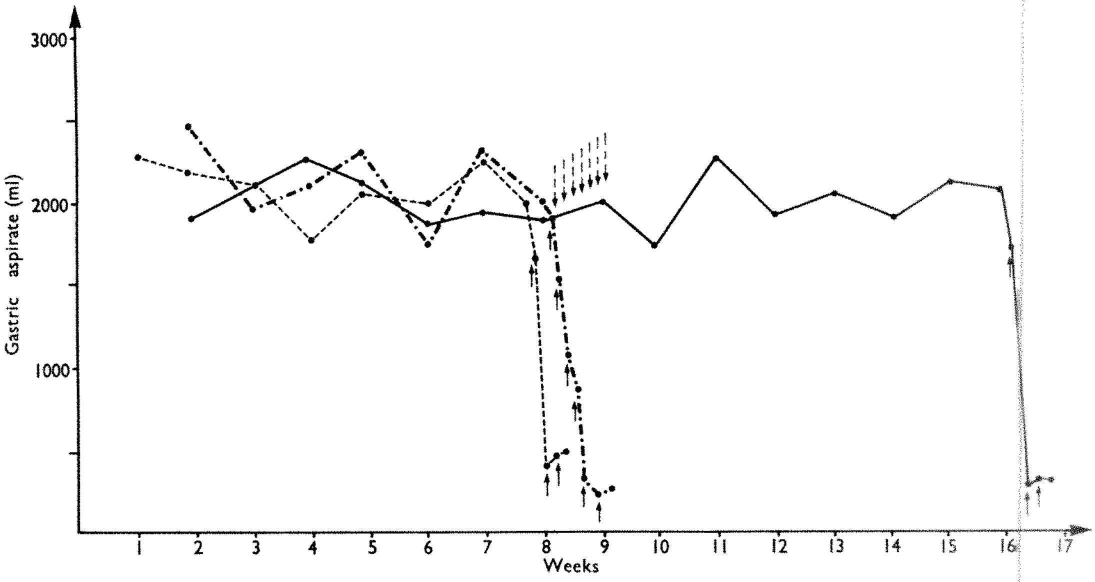

Fig. 1. Gastric aspirate curves. Arrows point to the days on which oxytocin was given. Dotted arrows point to the days on which bethanechol chloride and metoclopramide were administered in the first patient.

Once mechanical outlet obstruction has been ruled out, the usual treatment of postoperative atony is gastric aspiration and intravenous or jejunal feeding (Herman and Johnson, 1970). Recovery is spontaneous according to Kraft et al. (1964), who also claim that autonomic drugs have no effect. However, in some exceptional cases, mechanical decompression is insufficient to return the tonus of the gastric muscle to the level necessary for renewing gastric emptying. Contrary to the statement of Kraft et al. (1964), medical treatment may be beneficial. Bethanechol chloride has been successfully used (Bergin and Jordan, 1959; Sheiner and Catchpole, 1976). Metoclopramide has also been found to have some favourable effect in moderate cases (Stadaas and Aune, 1972; Sheiner and Catchpole, 1976). Carbachol has also proved to be effective in accelerating gastric emptying (Tinker et al., 1970). However, in our first case not only metoclopramide but also bethanechol chloride was unsuccessful and the patient remained in complete atony for 4 months. The unresponsiveness to these drugs may have been caused by the long delay between the operation and the onset of parasympathomimetic drug therapy.

Oxytocin is known to have a stimulant effect on the smooth muscle of the uterus and mammary gland. Goodman and Gilman (1975) state that its function, if any, in males is not known. When given for the induction of labour, no major effect on the gastrointestinal tract is observed. This probably results from the very small dosage necessary to obtain contraction of the gravid uterus. Moreover, it is possible that this is also due to the fact that in the gynaecological cases in which oxytocin is used the innervation of the gastrointestinal tract is presumably normal. Indeed, as Cannon (1939) has postulated in his 'law of denervation supersensitivity', it seems that denervation makes smooth muscle more susceptible to drugs. This has also been proved by Tinker et al. (1970), who found that subthreshold doses of carbachol provoke a significant acceleration of gastric emptying in vagotomized humans. Thus, although oxytocin has no effect on the intestines in induction of labour, it may be effective on the vagotomized stomach and this was the rationale of its use.

Autoparathyroidectomy: a case report

G. R. MCLATCHIE, E. W. MORRIS, A. FORRESTER AND I. FOGELMAN*

SUMMARY

This report describes a patient with primary hyperparathyroidism who became spontaneously normocalcaemic preoperatively. This was due to infarction in a parathyroid adenoma. Plasma parathormone (PTH) levels were monitored pre- and postoperatively.

SPONTANEOUS infarction of parathyroid adenomas resulting in a fall of serum calcium levels into the normal range is rare. It was first described by Norris (1946), but this is the first case report which includes details of the serum PTH levels.

Case report

A 51-year-old male presented to Glasgow Royal Infirmary with a 6-year history of increasingly frequent attacks of renal colic. In June 1976 an intravenous pyelogram (IVP) demonstrated a left hydronephrosis with ureteric dilatation to the 4th lumbar vertebra and a right renal pelvic calculus. After a left ureterolithotomy in late September 1976, the patient was noted to have repeatedly high fasting serum calcium levels with a low serum phosphate (*Table I*). Blood urea, plasma proteins and serum alkaline phosphatase were normal but plasma PTH was elevated to 1150 ng/l (normal range 500 ng/l). Iliac crest biopsy was histologically consistent with hyperparathyroidism. IVP demonstrated a large staghorn calculus in the right renal pelvis. The skeletal survey was normal.

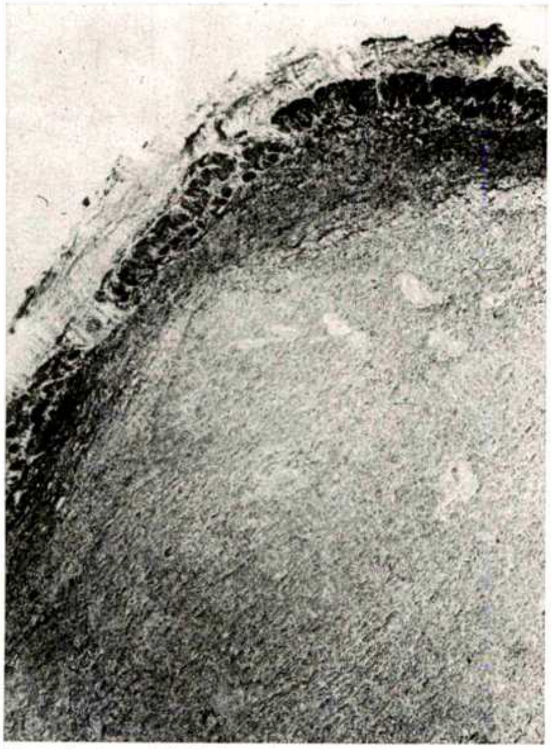

Fig. 1. Section of the infarcted parathyroid adenoma at low power showing an eosinophilic central area with peripheral normal glandular tissue. (×4.)

Table I: THE CHANGES IN SERUM CALCIUM, PHOSPHATE AND PARATHORMONE LEVELS BEFORE AND AFTER NECK EXPLORATION

Date	Calcium (mmol/l) (Normal = 2·2–2·6)	Phosphate (mmol/l) (Normal = 0·8–1·4)	Parathormone (ng/l) (Normal = <550 ng/l)
17.9.76	3·07	0·67	
15.10.76	3·42	0·52	
22.10.76	3·40	0·61	1150
9.1.77	2·30	0·95	
11.1.77	2·50	0·90	<190
20.1.77	Neck exploration		
21.1.77	2·15	0·65	
22.1.77	1·85	0·85	
24.1.77	2·05	0·80	
25.1.77	2·20	1·15	
26.1.77	2·15	1·10	<190

Correspondence to: G. R. McLatchie, 73 Novar Drive, Hyndland, Glasgow.

Serum calcium and PTH levels returned to normal immediately prior to neck exploration but these results were not available to us until during the postoperative period. Three suspicious enlarged parathyroid glands were removed at operation. The patient recovered uneventfully. To date PTH and serum calcium levels have remained normal.

Pathological findings

Histologically the 2-cm mass removed from the region of the left upper pole of the thyroid was an infarcted chief cell adenoma with appearances suggesting infarction of some weeks' duration (*Figs.* 1 and 2). The two other glands were histologically normal.

Discussion

Spontaneous infarction of parathyroid adenomas in hyperparathyroidism, producing normocalcaemia, is rare. Previous cases have been reported by Connor et al. (1965), Johnston and Schnute (1961), Norris (1946) and Northcutt et al. (1969) but in none of these cases was serum PTH monitored.

The fall of serum calcium following spontaneous infarction varies in severity from acute tetany to fatal hypocalcaemia (Dowlatabadi, 1959). Neck pain has also been reported as an accompaniment to infarction (Howard et al., 1953). The case we describe had none of these features preoperatively. This may be explained by the fact that he had been on 2 μg of 1-alpha-hydroxy-vitamin D_3 for the 10 days prior to his neck exploration and this could account for the unusual finding of normocalcaemia only 4 days after exploration and after the removal of two normal parathyroid glands (Boyle et al., 1977).

It is thought that those cases of apparent cure in which adenomas, though present, have not been found at neck exploration, are due to compromise of the blood supply of the parathyroid glands (McGeown and Morrison, 1959).

Acknowledgements

The authors wish to thank Mr I. McLennan, Mr J. S. F. Hutchison, Dr Ian Boyle and Professor R. Goudie for their assistance in the preparation of this case report. We would like to express our gratitude to Miss B. Maguire for secretarial help in the preparation of the manuscript.

Vascular Surgical Society of Great Britain and Ireland: Preliminary Notice

The Annual Meeting for 1979 is to be held in the newly opened John Radcliffe Hospital, Headington, Oxford, on Tuesday 18 December 1979. Overnight accommodation will be available before and after the meeting in Keble College where the Annual Dinner will be held. Transport by coach between Keble College and the John Radcliffe Hospital will be provided. The train service to Oxford is good and, if possible, should be used to avoid difficulties with car parking. Overnight luggage may be left in Keble College during Wednesday morning by Members staying on for Christmas shopping in the very fine bookshops nearby.

The local Secretary is Mr Howard Steer (Nuffield Department of Surgery, John Radcliffe Hospital, Headington, Oxford) who will circulate all members within the next few weeks giving further details of the meeting together with abstracts forms for those members wishing to offer papers; a 200 word summary will be required and the closing date for receiving this will be 10 October.

Tracheal collapse after thyroidectomy

W. E. R. GREEN, H. W. H. SHEPPERD, H. M. STEVENSON AND W. WILSON*

SUMMARY

Tracheal collapse after thyroidectomy is uncommon; when it occurs, complete airway obstruction is often sudden, unexpected and fatal.

In this paper a patient treated for tracheal collapse by tracheostomy and followed up for 1 year is described and, from a review of the literature, a further 9 cases are presented. The aetiology of the condition, the patient at risk and the technique of management are discussed.

SOME cases of acute respiratory distress occurring after thyroidectomy for benign disease have been attributed to collapse of the trachea. Softening of the rings and loss of support from the surrounding goitre have been proposed as the causes of sudden and unexpected airway obstruction (Henry, 1927) which may prove fatal (Cooke, 1966). Normal vocal cord movement, the absence of glottic or subglottic oedema and exclusion of haematoma make a diagnosis of tracheal collapse likely if respiratory difficulty is encountered during or shortly after operation (Henry, 1927; Peterson and Rovenstine, 1936; Mayer, 1951), or up to 24 h later when the patient has returned to the ward (Marangos, 1951; Cooke, 1966). It occurs after removal of a long standing, toxic and often intrathoracic goitre, though cases have been reported in which the gland was neither large (Henry, 1927) nor toxic (Mayer, 1951). The condition is uncommon, there being 3 cases in a series of 600 thyroidectomies described by Henry (1927) and only 1 in a larger series of 1000 (Peterson and Rovenstine, 1936), and although recognized as a definite clinical entity (Joll, 1932) it has received only brief mention in some reviews (Plested and Pollock, 1967; Black, 1972; Beaugie, 1975) and none in others (Montgomery and Welbourn, 1963; Wade, 1965; Freeman, 1970; Martis and Athanassiades, 1971; Barraclough and Reeve, 1975). There have been reports of successful restoration of the airway by endotracheal intubation or tracheostomy (Henry, 1927; Joll, 1932) and also cases where the patient died despite intubation (Peterson and Rovenstine, 1936; Marangos, 1951) or because the airway obstruction was recognized too late (Cooke, 1966). The longer term management of this condition, and the prognosis if successfully treated, have not been reported in detail.

Case report

A 36-year-old man with a 3-year history of thyrotoxicosis presented initially with weight loss, muscle weakness, irritability and a moderate goitre. Treatment with neomercazole 15 mg b.d., thyroxine 0·2 mg b.d. and propranolol 40 mg q.i.d. rapidly controlled his symptoms and he became stable on maintenance therapy of neomercazole 15 mg/day and thyroxine 0·2 mg/day. He was referred for surgical treatment because of the continued presence of a goitre, although this was not causing pressure symptoms. Examination revealed a healthy, well-built man with a mild degree of pectus excavatum. There was a smooth goitre of moderate size in the neck with an associated bruit but no evidence of thyrotoxicosis. The respiratory system was normal. A chest X-ray showed no evidence of intrathoracic extension of the goitre. Routine haematological and biochemical investigations were normal.

At operation (W. W.) a five-sixths subtotal thyroidectomy was performed removing 180 g from a moderately vascular goitre. The remnant of each lobe was sutured to the fascia on either side of the trachea, which was not noticeably abnormal. Recovery from anaesthesia was uneventful and the patient was extubated. Complete airway obstruction occurred immediately and the patient was reintubated without difficulty, at which time both vocal cords were seen to move normally. A second attempt at extubation failed and a tracheostomy was therefore performed. Again the trachea was not obviously abnormal, and there was no difficulty in inserting a 39 Portex cuffed tracheostomy tube; there was no evidence of local oedema or haemorrhage.

A satisfactory airway was maintained after tracheostomy, but on the first postoperative day signs of hypocalcaemia were observed (serum calcium 1·81 mmol/l) and the patient required calcium supplements for a further 7 days. Tomograms of the upper air passages showed considerable subglottic narrowing of the trachea (*Fig.* 1) but this narrowed segment expanded well during a Valsalva manoeuvre. X-rays were taken with the tracheostomy tube removed and the patient was able to breathe, although with very considerable inspiratory stridor. On the fourth postoperative day the Portex tracheostomy tube was changed to a size 28 Silver tube and the day after a further change was made to a 26 with a speaking valve.

The patient was unable to tolerate blocking of the tube at night, particularly when lying flat, but during the day a satisfactory airway was maintained. On the eighteenth postoperative day a bronchoscopy (H. M. S./W. E. R. G.) was performed; the vocal cords were normal and the trachea had an adequate lumen. The patient recovered quickly from anaesthesia and was able to maintain a satisfactory airway. The tracheostomy tube was not replaced. Some respiratory difficulty was again noted at night, particularly with the clearing of secretions; sleeping well propped up was found to be most comfortable. Over the next 2 days stridor during a normal respiratory effort disappeared, and the patient's voice, which had been moderately hoarse after extubation, improved.

A laryngoscopy (H. W. H. S.) was performed on the twenty-second postoperative day, which showed normal cord movement but still some narrowing of the trachea, which appeared as an anterior/posterior slit tending to collapse inwards during inspiration. The patient continued to improve and one month after operation the tracheostomy wound had closed, there was minimal inspiratory stridor on exertion, he was able to cough and clear secretions and to sleep lying flat without distress.

Follow-up at 1 year has revealed a satisfactory outcome; the patient remains euthyroid, with a normal voice and no respiratory distress either at rest or during exertion. Further radiographs of the larynx and trachea have revealed some degree of subglottic narrowing (*Fig.* 2) which appeared to be at the level of the original collapse; on tracheoscopy, however (H. W. H. S.), a stricture at the level of the original tracheostomy was found and the distal trachea was normal.

Discussion

Aetiology

It has been suggested that a firm goitre of long standing, crowding the trachea, may lead to loss of elasticity and even disappearance of the rings (Henry, 1927); removal of the surrounding gland may then

result in collapse of the unsupported airway. Displacement or deformation of the trachea, without softening, is unlikely to result in airway obstruction (Henry, 1927) since the natural resilience of the rings will permit it to spring open (Lahey and Hoover, 1951). An alternative hypothesis of tracheal spasm was investigated experimentally in the dog by Cole (1939), prompted by his own experience of serious stridor in a patient undergoing thyroidectomy. He concluded that although spasm of the trachealis muscle could produce some narrowing of the normal trachea it did not induce collapse, and a negative airway pressure of −70 mmHg also failed to narrow the lumen by any greater amount than that produced by muscle spasm. It was felt that although respiratory difficulty and stridor might at times be associated with mechanical changes in the configuration of the lumen, collapse of the walls with complete obstruction was unlikely to occur unless the trachea was pathologically soft.

The patient at risk

The condition, despite the uncertainty as to its cause, has been recognized for many years (Joll, 1932; Marangos, 1951; Cooke, 1966), although the patient at risk, generally assumed to be the treated thyrotoxic case, has not been clearly defined. In this review of the reported cases (*Table I*) it was found that although more of the patients had at some time been thyrotoxic, the condition did not occur exclusively in this group nor was the size or position of the goitre of predictive value; all the patients appeared to have had thyroid dysfunction for more than a year but information on

Table I: TRACHEAL COLLAPSE: DETAILS OF 9 CASES

Series	Goitre	Toxic	Recognized at op.	Treatment	Result	Time of death
Henry (1927)	Moderate	Yes	Yes	Endotracheal tube	Alive	—
	Moderate	Yes	No	Endotracheal tube	Alive	—
Joll (1932)	Moderate	Yes	No	Tracheostomy	Alive	—
Peterson and Rovenstine (1930)	Large	Yes	Yes	Endotracheal tube	Died	6 h
Mayer (1951)	Large	No	Yes	Endotracheal tube	Alive	—
Marangos (1951)	Small	No	No	None	Died	12 h
	Large intrathoracic	No	No	Tracheostomy	Died	3 h
	Moderate	No	Yes	Tracheostomy	Alive	—
Cooke (1966)	Moderate	Yes	Yes	None	Died	24 h

the exact length of time for which a goitre had been present was not available. Marangos (1951) has emphasized the need to examine the trachea at operation for evidence of softening, but in many patients, including our own, this has not proved helpful in anticipating subsequent airway obstruction due to collapse.

The crisis may occur during the operation if the procedure is performed without endotracheal anaesthesia (Henry, 1927; Peterson and Rovenstine, 1936; Mayer, 1951) or during the recovery period as respiratory effort increases, sometimes up to 24 h after operation (Marangos, 1951; Cooke, 1966). Symptoms of respiratory difficulty usually appear suddenly, without warning, and progress rapidly to complete airway obstruction. In the cases reviewed there was a mortality of 44 per cent.

Management

There has been no clear guidance on the management of this condition. If recognized at operation, suturing of the trachea to the soft tissues of the neck has been advocated (Henry, 1927; Joll, 1932; Peterson and Rovenstine, 1936) although it is difficult to believe that this manoeuvre would be sufficient to hold the airway open against the negative pressure of inspiration, and in the one case reported in which this was done the patient subsequently required tracheostomy when the trachea collapsed and became obstructed 12 h after operation (Marangos, 1951).

Intubation has been employed for as long as 24 h (Henry, 1927) and as little as 3 h (Mayer, 1951). Peterson and Rovenstine (1936) have stressed that a trachea which has collapsed is likely to do so again, citing a patient, extubated after only 6 h, who died a short while later of asphyxia due to sudden reobstruction of the airway. In a general review of airway obstruction associated with thyroid disease, Lahey and Hoover (1951) stressed that mediastinitis was not a problem if tracheostomy had to be performed in association with thyroid surgery.

The sudden complete airway obstruction requires urgent relief and, although temporary respite may be gained for the patient by face-mask ventilation or mouth-to-mouth rescuscitation, a definitive procedure must be performed without delay.

Coniotomy (Oppenheimer, 1974) and needle tracheostomy (Lee, 1978) are both inappropriate in this situation as the entry point into the trachea is certain to be above the part which has collapsed; the choice therefore lies between endotracheal intubation and tracheostomy. The use of PVC tubes and low pressure 'floppy' cuffs has greatly diminished the risk of tracheal injury after prolonged intubation by either route (Cooper and Grillo, 1972; Crawley and Cross, 1975) and stenosis is most likely to occur at the site of the stoma after tracheostomy (Friman et al., 1976), particularly if this has been carelessly or incorrectly fashioned (Lulenski and Batsakis, 1975). In this situation, where the trachea is already abnormal and possibly distorted, endotracheal intubation, if possible, is to be preferred. On the other hand, time should not be wasted trying to perform a difficult intubation when reopening of the wound will expose a trachea already bare of veins and thyroid tissue. The final choice must depend very much on the time and place at which the crisis occurs and the skill of the clinician at hand.

Intubation is required for at least 24 h, and if tracheostomy has been performed the softened airway, further weakened by the creation of a stoma, may require splinting for a considerably longer period. Patients managed with an endotracheal tube can probably be extubated after 24–48 h provided that facilities are available for its replacement, if necessary. Patients with a tracheostomy may be treated either by progressive reduction in the size of the tube, as in our own case, or by trial removal of the tube at 5 days. In our own experience although some lateral movement of the tracheal wall may be seen and clinical stridor persist for some days, neither is an indication to prolong intubation.

Longer follow-up of our own case has confirmed that tracheostomy is not without risk to the integrity of the airway, although the radiological and endoscopic findings do not correlate with the clinical condition of the patient.

Conclusion

From this review it appears that collapse of the trachea, although uncommon, may occur in any patient undergoing thyroidectomy; the individual at risk does not appear to be determined by the nature of the thyroid disorder, nor by the size or position of the goitre. Respiratory difficulty may present unexpectedly at any time during the first 24 h after operation and is likely to prove fatal unless treated immediately.

Immediate restoration of the airway is essential, after which the diagnosis can usually be made by exclusion of cord paralysis, oedema and haematoma. The airway should be maintained by intubation for a minimum of 24 h and for a more prolonged period if respiratory distress continues.

The choice between endotracheal intubation and tracheostomy is more likely to be determined by the skill of the clinician on hand at the time of the crisis although endotracheal intubation may be preferable to tracheostomy if subsequent stenosis of the trachea is to be avoided.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Carcinoma of the thyroid

T. T. ALAGARATNAM AND G. B. ONG*

SUMMARY

Total thyroidectomy with excision of any enlarged cervical lymph nodes was the usual operation practised for carcinoma of the thyroid in this series. Extended thyroidectomy afforded cures in some patients with locally advanced disease. Preoperative drill biopsy of the goitre was a useful procedure. Other noteworthy features were the increasing occurrence of papillary carcinoma and the comparatively high incidence of malignancy in solitary nodules.

CARCINOMA of the thyroid is an uncommon tumour which accounts for 0·7 per cent of all cancers in women and 0·2 per cent in men (Waterhouse, 1974). Patients in the present review were all admitted to the University Surgical Unit at the Queen Mary Hospital, Hong Kong. The unit deals with all types of surgical case, so that the patients were in no way selected. They were operated on by surgeons of varying experience from registrars to consultants. Goitre has not been an endemic illness in Hong Kong and the present review is of a population in which goitre is no more frequent than other major illnesses.

From 1964 to 1976 there were 124 cases all of which were histologically proved to be malignant. The classification recommended by the WHO was used; the histology of earlier patients was reviewed and reclassified. Twelve patients who were lost to follow-up were excluded.

Patients and methods

Incidence

Over the 13 years there has been a gradual increase in the incidence of thyroid carcinoma (*Table I*). In 1964, there were 9 cases of carcinoma: follicular carcinoma comprised 55 per cent and papillary carcinoma, 11 per cent. A third of the 9 cases were in the 41–50 age group. In 1976, there were 26 cases of carcinoma, and the increase was mostly in the 21–30 age group. Papillary carcinoma (39 per cent) showed a striking increase (almost fourfold), whilst the incidence of follicular carcinoma was slightly diminished (43 per cent). During this period 751 cases of benign goitre underwent surgery, giving an overall operative incidence of 16 per cent for carcinoma.

The incidence in terms of age and the proportion of males in the series is shown in *Figs*. 1 and 2 respectively. Follicular carcinoma shows two 'peaks', one in the younger (20–30) and the other in the older (50–60) age group. In the latter group, anaplastic carcinoma was also frequent. In the elderly male patients follicular carcinoma and anaplastic carcinoma were most frequently encountered; in younger men papillary carcinoma was more frequent. The overall incidence in males was 21 per cent. There were no cases of carcinoma in children in the present series.

Follicular carcinoma was the most common, followed closely by the papillary variety (*Table II*). There were 13 cases of anaplastic carcinoma and 3 cases of medullary carcinoma. Malignant lymphoma was a rare lesion. Two cases of laryngeal carcinoma presented clinically as a thyroid swelling; and one patient with carcinoma of the breast developed a metastatic nodule in the thyroid. These 3 cases have been excluded from the series.

Mode of presentation: A clinical diagnosis of thyroid carcinoma was possible in 17 per cent of the series. Unmistakable features of carcinoma such as a recent rapidly enlarging goitre with

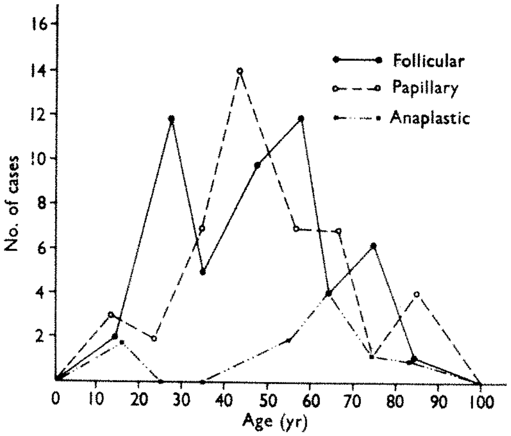

Fig. 1. Distribution by age of carcinoma of the thyroid.

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Already used widely in serious infections

cefuroxime sodium

Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics.

Zinacef resists destruction by beta-lactamases
A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.

Zinacef is effective against:

- **most common pathogens**
- **many uncommon pathogens**
- **multi-antibiotic resistant pathogens**

ZINACEF, A BROADER SPECTRUM THAN MOST ANTIBIOTICS

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 grams and infusion pack of 1·5 grams. All containing cefuroxime as cefuroxime sodium.
Indications
Serious bacterial infections, especiall where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft-tissue infections
Obstetric and gynaecological infection
Bone and joint infections
Ear, nose and throat infections
Meningitis
Gonorrhoea
Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 grams t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary, giving total doses of 3 grams to 6 grams daily.
Infants and Children: 30 to 100mg/kg/day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in tw or three divided doses.
Gonorrhoea: Single dose of 1·5 grams (2 x 750mg i.m. into different sites).
Contra-indications
Hypersensitivity to cephalosporins.
Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria. Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage shoul be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.
Side effects
Adverse reactions are rare and generally mild and transient, e.g., rashes, gastro-intestinal disturbance candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).
Storage
Protect from light.
Product Licence number: 4/0263
Price to Hospital (exclusive of VAT)

5 x 250mg	£0·70 per vial
5 x 750mg	£2·10 per vial
1·5 grams	£4·20

A new generation of Micra Titanium Instruments.

Downs Surgical's new range of Micra titanium forceps offers advances in design and quality with a complete choice of delicate tips.
This new generation of Micra titanium forceps incorporates the requests for improvement revealed in a world-wide survey of Micra Instrument users.
Now these improvements are made possible due to our improved titanium technology.
Straight, curved and colibri forceps are available with tying platforms on tying, notched and toothed tips or as plain forceps.

For full details just return the coupon.

Downs Surgical
Simply the best.

Downs Surgical Limited, Church Path, Mitcham, Surrey CR4 3UE England.

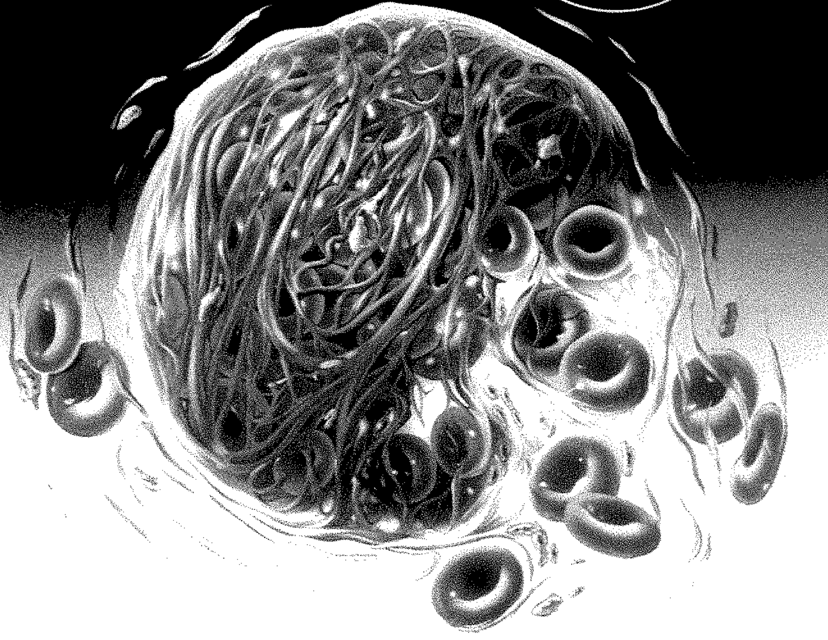
Announcing the availability of

ABBOKINASE®
urokinase for injection



The first tissue-culture urokinase for the treatment of pulmonary embolism.

With significant advantages, both clinical and practical, over other thrombolytics, anticoagulant therapy and surgery.

- **Abbokinase achieves rapid clot lysis by a direct action on the fibrinolytic mechanism. Urokinase has a greater affinity for plasminogen within the formed clot (gel phase plasminogen) than for circulating plasminogen (sol phase plasminogen)[1] and is therefore the most selective thrombolytic agent in current use.[2]**
- **Abbokinase is devoid of antigenic activity in humans – unlike streptokinase. This obviates prior antibody testing and the need for corticosteroids for the prevention and alleviation of allergic response.[3]**
- **Abbokinase is more successful than anticoagulants which do not lyse the clot or reopen the vessel.[4,5]**
- **Abbokinase is more economical and less traumatic than surgery.**

Data sheet information: **Presentation** Abbokinase is available in 10ml vials containing 250,000iu of a highly purified sterile lyophilised formulation of urokinase obtained from cultures of human kidney cells. Urokinase is a plasminogen activator excreted in the urine of normal healthy individuals. When reconstituted with 5.2ml distilled water according to directions, each ml of isotonic solution will contain 50,000iu urokinase, 5mg mannitol and 9mg sodium chloride. **Uses** Abbokinase in vivo and in vitro produces the release of plasmin by an enzymatic action on human plasminogen. Abbokinase has only minimal activity in reducing fibrinogen levels but blood plasminogen levels are reduced, the effect being dose-dependent. Abbokinase is virtually non-antigenic to humans and, in therapeutic doses, is thromboplastin-free. Thrombolytic therapy is indicated in the treatment of vascular occlusions caused by forming or recently formed fibrin clots. Theoretically the best results will be obtained with thrombi less than 24 hours old. Abbokinase is indicated as a thrombolytic agent in pulmonary embolism. **Dosage and Administration** Abbokinase is administered intravenously by continuous infusion, usually for a period of 12 hours. It is recommended that Abbokinase be given in a solution of Normal Saline by constant infusion. An initial loading dose to be given during the first ten minutes of therapy is advocated. This loading dose should be equal to the amount which it is planned to administer over each succeeding period of one hour. Ideally an infusion pump should be used to maintain a constant rate of infusion. Abbokinase is reconstituted with 5.2ml sterile water for injection, without preservatives. For administration the reconstituted solution should be further diluted with normal saline to the total volume of solution (195ml) for a 12 hour treatment including the priming dose. From this solution, 15ml are given over a period of 10 minutes as the priming dose and the remainder over a period of 12 hours at the rate of 15ml/hour. Dosage: It should be noted that patient-to-patient variation in response can be expected, due to individual variation in levels on inhibitory factors. Certain disease states such as uraemia, some malignancies and dyslipidaemias can be associated with an increased plasma level of urokinase or plasmin inhibitors. In other conditions such as massive pulmonary embolism, endogenous fibrinolytic activity may be increased. The recommended dosage regimen for the treatment of pulmonary embolism is: Loading dose: 4,400iu per kg bodyweight over 10 minutes. Constant infusion dose: 4,400iu per kg bodyweight per hour. Duration of infusion: 12 hours. **Contra-indications, Warnings, etc.** Contra-indications: Manifest or recent (i.e. within 3 days) haemorrhage. Any haemorrhagic diathesis. Severe hypertension. During cardiopulmonary resuscitation. During pregnancy or suspected pregnancy. Warnings and Precautions: The major adverse effect of Abbokinase is haemorrhage, usually associated with too high dosage. A high incidence of bleeding from minor skin lesions, therapeutic and diagnostic puncture sites and pre-existing gastro-intestinal lesions has been observed with high dosages. Any evidence of significant internal bleeding necessitates the cessation of thrombolytic therapy. An anti-fibrinolytic agent such as epsilonaminocaproic acid (EACA) may be used as an antidote if required. Epsilonaminocaproic acid should be available for use, if necessary, during infusions with Abbokinase when high doses are being administered. Post-partum for one month. Recent surgery (within 3 days). Concurrent anti-coagulant therapy should be administered cautiously. Mild temperature increases have been observed during thrombolytic therapy with Abbokinase. When there is a history of hypersensitivity to drugs etc., caution is advised and facilities as well as corticosteroids, adrenaline, etc. should be readily available when Abbokinase is infused. Monitoring: The monitoring of fibrinolytic activity and of plasminogen levels is desirable. Pharmaceutical Precautions: The lyophilised powder should be stored at 2-8°C. Reconstituted solution should be used immediately after mixing and secondary dilution. **Legal Category** POM. **Package Quantities** Available in packs of 2 vials of 250,000iu each (List No. 6109). **Further Information** The potency of Abbokinase is expressed in International Units (iu). For practical purposes the iu is considered by most authorities to be equivalent to the CTA unit. The Ploug unit is usually considered to be equal to 1.4iu. **Product Licence Number** 0037/0096. **References** 1. Kakkar V.V, Scully M.F. Thrombolytic therapy *Brit. Med. Quite an operation

When it comes down to it, any operation can only be rated successful if it produces the required result. And tying up the loose ends is important at the end. Thats why Key Med's operation maintains a veritable army of specialists—a skilled task force of experts, disciplined not only to meet the needs of today, but to anticipate and deal with the challenges of the 80's. To ensure that you receive a complete package of products and services, calculated to meet any eventuality.

But we also believe in after-sales service and problem solving. The best briefing in the world can hit snags when practice replaces theory. We are reactors in every sense of the word. And the main link in our chain is to be on-call when required. Which, we're happy to report, isn't often! Key Med is geared up to produce confidence at the outset, and success at completion. A value for money operation you should know more about.

hard areas, widespread skin and muscle involvement, or the presence of enlarged hard cervical lymph nodes simplified the diagnosis. In 2 patients the tumour had ulcerated. In a further 13 per cent malignancy was suspected at the initial clinical examination, though no overt clinical signs were present. In 70 per cent of patients, however, the presentation was that of a clinically benign goitre and malignancy was diagnosed on histology alone. The majority of thyroid carcinomas presented as solitary nodules, and, when compared with benign nodules seen over this period, the incidence of malignancy in solitary nodules was 25 per cent. Solitary nodules were present in all age groups, but were most frequent in the 30–50 group. Five patients in the present series had been treated for thyrotoxicosis. Four patients were treated with anti-thyroid drugs and one had undergone subtotal thyroidectomy. Twenty-three per cent of the cases presented with a multinodular goitre.

The type of goitre giving rise to carcinoma is shown in *Table III*. Follicular carcinoma was more common than the papillary variety in multinodular goitres and these usually presented in an older age group than solitary nodules; toxicity appeared to be more often associated with follicular than papillary carcinoma. Palpable cervical lymph nodes were present in only 2 cases of follicular carcinoma. In 8 cases of papillary carcinoma, clinically palpable (and histologically proved) lymph nodes were present. In another 11 cases, enlarged lymph nodes were found at operation, and of these 6 were free of tumour. In the majority of patients with papillary carcinoma the tumour was found to have breached the capsule of the thyroid gland and early infiltration to adjacent structures was observed. There were only 4 cases of occult papillary carcinoma. Early presentation was certainly not a feature in our patients. Only 20 per cent presented with a history of less than a year; the majority presented with a history of between 2 and 8 years with a median of 6 years. The commonest reason for seeking treatment was a gradual increase in the size of the goitre. In 10 per cent of the patients, however, the goitre had been present for 10–30 years with a median of 25 years. Recent rapid increase in size with symptoms relating to pressure on the trachea or oesophagus had eventually prompted presentation. In cases of anaplastic carcinoma the majority of patients presented with severe compression symptoms such as breathlessness, hoarseness, dysphagia and a persistent cough of short duration. In all types of carcinoma, the commonest compression symptom when present was dyspnoea, followed closely by hoarseness and dysphagia. Pain was an occasional symptom.

Drill biopsy: Since 1971 it has been our routine procedure to perform drill biopsy in all patients with thyroid lesions using a pneumatic drill fitted with a hollow needle. Over 400 patients have had this procedure performed with few complications (Ma et al., 1975). In the present series, drill biopsy was performed in 42 cases; in 25 patients (59·5 per cent) the biopsy was helpful in detecting malignancy of all histological types. Only 3 of the 42 patients had overtly malignant lesions. Preoperative biopsy was thus of great value in confirming malignancy in those who presented with goitres that clinically appeared to be benign. In particular drill biopsy enabled the surgeon to perform a planned total thyroidectomy for follicular carcinoma rather than a two-stage thyroidectomy necessitated by equivocal frozen sections of the tumour at the initial operation. Needless to say, such reoperation is hazardous, even for the most experienced surgeon. In 1971 there were 4 of a total of 6 patients who required such a two-stage total thyroidectomy. In 1976, with greater experience in interpreting histology from the small piece of tissue obtained by drill biopsy, 5 of a total of 12 patients required reoperation.

Treatment

Follicular carcinoma: All 50 cases of follicular carcinoma were treated by total thyroidectomy; in some, for reasons mentioned earlier, the operation was staged, the remaining lobe of the gland being excised 2–3 weeks after the initial operation. In 2 patients with advanced local disease, extended thyroidectomy was performed. One of the patients survived for 6 years and the other was lost to follow-up after 3 years.

Papillary carcinoma: Total thyroidectomy was performed in 25 cases, and hemithyroidectomy in 20. Nineteen patients had associated enlarged cervical lymph nodes which were excised. No formal radical block dissections of the neck were performed. Four patients who initially had hemithyroidectomy returned with tumour in the opposite lobe 6–10 years later. Extensive local recurrence after total thyroidectomy occurred in 1 patient and extended thyroidectomy afforded good palliation for 6 years.

Table III: TYPE OF GOITRE GIVING RISE TO CARCINOMA

	Follicular	Papillary	Anaplastic
Multinodular goitre	12	7	6
Solitary nodule	34	37	7
Associated with thyrotoxicosis	4	1	—

Table IV: SURVIVAL BY AGE

Age at presentation	Type of carcinoma	5-year survival (%)	10-year survival (%)
< 50 years	Papillary	75	40
	Follicular	66	30
> 50 years	Papillary	65	40
	Follicular	54	20

Anaplastic carcinoma: In this group total thyroidectomy was performed in 6 of the 13 patients; partial thyroidectomy was performed in 2 patients; in a further 2 patients, advanced local disease permitted only local resections around the trachea, without any form of thyroidectomy. All patients were given postoperative external irradiation. One patient presented with such advanced local disease that only external irradiation was possible. Extended thyroidectomy involving laryngectomy and partial excision of the oesophagus was performed in 2 patients; both patients, however, succumbed from leaks at the oesophageal suture line.

Medullary carcinoma: There were only 3 cases of medullary carcinoma and all were treated by total thyroidectomy. One case presented with a massive retrosternal extension requiring a combined cervical and total sternum-splitting incision.

Results

Operative mortality

There were 4 deaths. In addition to the 2 patients mentioned earlier who died from extended thyroidectomy for anaplastic carcinoma, one patient died from cachexia due to advanced disseminated disease which was not detected preoperatively. Uraemia due to coexisting chronic pyelonephritis was the cause of death in another patient.

Complications

Two of the major complications following total thyroidectomy are hypoparathyroidism and damage to the recurrent laryngeal nerves. In the present series there was a 9 per cent incidence of tetany, which frequently occurred following a planned total thyroidectomy rather than following a two-stage thyroidectomy for follicular carcinoma. The incidence of permanent recurrent laryngeal nerve damage was 2·6 per cent. There was no damage to the cervical sympathetic chain. Reoperation for evacuation of a haematoma was necessary in 2 cases.

Survival

The overall survival for papillary carcinoma was 70 per cent at 5 years and 40 per cent at 10 years. In follicular carcinoma it was 50 per cent and 25 per cent respectively. Patients with anaplastic carcinoma fared poorly—there was only 1 survivor at 5 years. Survival figures for male patients were definitely inferior; there were no 10-year survivals among the males. Younger patients (less than 50 years) fared better than older ones (*Table IV*).

Discussion

The increasing incidence of papillary carcinoma, particularly in younger patients, appears in most series. In his review Crile (1971) has commented on the almost doubled increase in papillary carcinoma occurring in a relatively younger age group. Similar increases have been noted by Beahrs et al. (1951), Campbell and Sage (1975) and Heitz et al. (1976). Explanations for such an increase are hard to find. None of our patients had any history of childhood irradiation to the head and neck, nor was any exposed to atomic irradiation. Doniach (1969) suggested than an increased intake of iodine could be a factor, but there is no evidence to suggest that this is so in our local population. An increasing awareness of thyroid carcinoma and refinements in the histological diagnosis of carcinoma by pathologists would perhaps be partly responsible for the increasing incidence of carcinoma; but its occurrence in a younger age group is at present inexplicable. In most series papillary carcinoma appeared to be the predominant cancer; whilst this is true in non-endemic areas, in an endemic area such as Cali, Colombia, Wahner et al. (1966) noted a predominance of follicular carcinoma. In the present series there is an even balance between the papillary and follicular forms. There were only 3 cases of medullary carcinoma and none of them were familial or associated with phaeochromocytoma.

The commonest mode of presentation was a solitary nodule. When compared with similar benign nodules, the incidence of malignancy was 25 per cent; this is much higher than that quoted in most series. The incidence of malignancy in multinodular goitre has been around 10 per cent (Cope et al., 1949, 10 per cent; Crile and Dempsey, 1949, 10·9 per cent). In the present series it was 9 per cent. Diagnosing malignancy preoperatively in a multinodular goitre has always been a difficult problem. It is slightly easier in a male patient with multinodular goitre in a non-endemic area; these should be viewed with great suspicion as thyroid carcinoma in males is more common than in females with goitre.

The dependence of thyroid carcinoma for its continued growth on thyrotrophic stimulating hormone has been firmly established by experimental and clinical observations. Surgical removal of the tumour followed by thyroxine therapy has now come to be accepted treatment. However, the extent of the operation has been a controversial question. Papillary carcinoma has been shown to be multifocal and the extent to which this has been observed to occur has depended on the thoroughness of examination of the gland removed at operation or at autopsy. Figures from 78 per cent (Clark et al., 1969) to 20 per cent (Block et al., 1960) have been reported. Total thyroidectomy would appear therefore to be the ideal treatment for papillary carcinoma. In the follicular variety, total thyroidectomy is essential to facilitate treatment of metastases by radioactive iodine; it also ensures removal of any tumour in the opposite lobe occurring as a result of intraglandular spread. The operation of total thyroidectomy, however, is not without its complications, permanent hypoparathyroidism being one of them (2 per cent reported by Thompson et al., 1973, to 33 per cent reported by Harold and Wright, 1966). Lesser operations have been performed, but these are not without their problems. McLintock (1968) has reported a 19 per cent recurrence after bilateral subtotal lobectomy; 13 per cent after lobectomy alone; and 6 per cent for lobectomy on the primary side and subtotal lobectomy on the contralateral side. Subtotal thyroidectomy with postoperative ablation of the remaining thyroid with radioactive iodine must always be a second-best procedure. Normal thyroid tissue would be certainly destroyed, but if tumour cells were present in the remaining thyroid tissue, then early recurrence is a probability as only 35 per cent of follicular carcinomas and 20 per cent of papillary carcinomas take up radioactive iodine (Scott, 1974). Another feature of papillary carcinoma which lends support to the idea of total thyroidectomy has been the late occurrence of a second carcinoma in patients who have had an initial lobectomy—Russell et al. (1969) recorded 4 per cent; Tollefson and De Cosse (1963), 3·7 per cent; Block et al. (1960), 7 per cent. Although these figures indicate an infrequent occurrence of a second carcinoma, the present writers agree with Hirabayashi and Lindsay (1961) that total thyroidectomy is still the best treatment for papillary carcinoma. This has been practised whenever a preoperative diagnosis (by drill biopsy) was possible. When, however, in an apparently 'benign' adenoma, the subsequent paraffin section revealed carcinoma, a second operation was not performed as the risk of inflicting permanent hypoparathyroidism was greater than the risk of a second carcinoma developing in the opposite lobe.

Taylor (1974) advocates total thyroidectomy only when the cervical lymph nodes are enlarged, believing that intraglandular spread to the opposite lobe occurred more frequently in such a situation. Four patients with papillary carcinoma who had unilateral lobectomy performed in the earlier years of the present series returned subsequently with tumours in the opposite lobe. In none of these patients was there any evidence of intraglandular spread at the initial operation. All 4 patients, however, had stopped taking thyroxine 1–2 years after surgery, and it is interesting to speculate whether recurrence would have occurred had they taken thyroxine regularly. In none of these patients was there any change in the histology from a well-differentiated form to a more anaplastic type.

In recent years, the trend in thyroid surgery has been away from radical or extended operations; few, if any, would perform standard radical block dissection of the neck or dissect the mediastinum for enlarged lymph nodes. Extended operations involving resection of the larynx, trachea or oesophagus are also infrequent, possibly because patients are now presenting for treatment at an earlier stage of the disease. Dajillian et al. (1974) recorded 6 survivors for periods varying from 5 months to 5½ years without evidence of local recurrence after total or partial laryngectomy as part of an extended operation. Although the morbidity and mortality are high, the present writers feel that there is still a place for such operations when the patient is first seen with extensive disease at an advanced stage in the neck, or with local recurrence. In the present series 2 of the 5 patients who underwent operation were able to live for 5 and 6 years respectively.

Patients with papillary carcinoma had a more favourable prognosis than those with follicular carcinoma. Other features such as male sex, age over 50 and extra-thyroid disease have been shown to be consistently associated with a poorer prognosis. These findings have been confirmed in this present series. The late presentation of many of our patients accounts for the slightly poorer survival values when compared with most Western series. One interesting feature which has been discussed in many large series is the effect of enlarged lymph nodes on prognosis. Some believe that the presence of metastatic cervical lymph nodes is associated with a better prognosis and a lesser mortality (Hirabayashi et al., 1961; Clark et al., 1967). Cady et al. (1976), in a review of four decades of thyroid surgery in the Lahey Clinic, have found evidence for this view. In the present study, however, there was no evidence to suggest that patients with tumour-bearing lymph nodes fared better than those without.

Acknowledgements

We wish to acknowledge the help of the Department of Pathology and in particular Dr P. M. Bannatyne who reclassified some of the earlier histology.

Experiences with head injuries in a regional neurosurgical unit

R. V. JEFFREYS AND N. I. AZZAM*

SUMMARY

A review of all patients with major head injuries transferred to a regional neurosurgical unit for the years 1975 and 1976 has been carried out for comparison with the total number of patients with head injury admitted to district general hospitals of the region. Fifty-four per cent of patients admitted to the neurosurgical unit have resumed their old occupation and 20 per cent died. The significance of these figures is discussed, particularly in the light of the need for a more comprehensive policy for treating head injuries within the United Kingdom.

IN the United Kingdom the number of patients admitted to hospital suffering from a head injury has reached epidemic proportions. For example, in 1972 the figure was 142 000 (*Epidemiology of Head Injuries in England and Wales*, 1976). The majority ultimately make full recoveries. However, there is a group who either have a disastrous head injury from the outset or develop major complications which require neurosurgical treatment. In an attempt to enumerate the latter, the extent of therapy required and the success rate for all this effort, a retrospective survey has been carried out on all cases with head injuries transferred to the Mersey Regional Department of Surgical Neurology for the years 1975 and 1976, thereby allowing a minimum follow-up time of 1½ years.

Policy

The Mersey Regional Department of Surgical Neurology is the sole neurosurgical unit responsible for the Mersey Regional Health Authority, the Area Health Authorities of Clwyd and Gwynedd and the Isle of Man Health Board. There is a potential catchment area of 3·25 million. Cases of minor head injury are not transferred. Head injuries are transferred at the request of surgeons and physicians in the district general hospitals, who are encouraged to telephone and discuss problems. Advice is given over the telephone and either further therapy is undertaken at the district general hospital or the patient is transferred. The reasons for transfer are:

1. Deterioration in level of consciousness and/or a worsening neurological deficit.
2. Unconsciousness for more than 4 h after injury and severe problems for the staff at the district general hospital.
3. Surgical problems such as CSF rhinorrhoea or a depressed skull fracture.
4. Long term complications such as chronic subdural haematoma and post-traumatic hydrocephalus.

Patients and methods

Two hundred and forty-eight patients were transferred to the neurosurgical unit from January 1975 to December 1976: 93·5 per cent came in as emergencies and 6·5 per cent as a result of late complications developing more than 10 days after head injury. All survivors have been followed up for periods in excess of 18 months but 22 were lost to long term study.

Therapeutic considerations

Skull X-rays had usually been performed in the referring district general hospital. In a rapidly deteriorating patient with a suspected intracranial haematoma burr hole exploration was done followed, if necessary, by exploratory craniotomy. If it was thought that there was time for the investigation, angiography was carried out; 45 per cent of the admissions were so investigated. This series antedates computerized axial tomography, which has now totally replaced angiography. All haematomas, whether subdural, extradural or intracerebral, causing displacement of the brain and/or a rise in intracranial pressure were explored surgically and evacuated either through burr holes or a craniotomy. Depressed fractures were explored and elevated. All unconscious patients and patients in whom it was considered that there was evidence of cerebral contusion and/or laceration were treated with dexamethasone. Intermittent intravenous injections of 20 per cent mannitol were used for severe episodes of raised intracranial pressure. If there was any question of respiratory insufficiency as judged by blood gases, intermittent positive pressure respiration was used for the first few days through an endotracheal tube and a tracheostomy was performed if continuing ventilation was required thereafter. All unconscious patients were so treated for the first 24 h and, provided that some progress was made, treatment was continued. All patients were so treated for the first 24 h and provided some progress was made, treatment was continued. In patients exhibiting evidence of cerebral death after a minimum of 24 h therapy, life support systems were withdrawn.

Results

Age and sex

There were 185 males and 63 females. *Fig.* 1 analyses the age distribution of the patients and clearly demonstrates that the patients most commonly encountered are in the first three decades of life. Younger patients are frequently seen, but they are less likely to die (*Fig.* 2).

Mode of injury

The mode of head injury usually falls into one of five main subdivisions (*Table I*). Injury at home and in road traffic accidents is more frequent than during sport or at work.

Clinical condition

An almost equal number of patients were found to be conscious, drowsy or unconscious at the initial admission and following transfer to the neurosurgical unit. However, there was an increase of 21 per cent in the number of patients who developed neurological deficit in the time elapsing between admission to the district general hospital and transfer to the neurosurgical unit (*Table II*).

Classification and treatment

Any classification of head injuries has to be crude; for example, an extradural haematoma may well be associated with *contre-coup* contusion. Based upon clinical, radiographic and surgical findings, the primary

Table VI: MORTALITY RATES IN VARIOUS SERIES

Study	Mortality rate (%)
Kerr, 1971	10·8
Klonoff and Thompson, 1969	13·6
Jennett et al., 1977	14·0
Present series, 1978	19·7

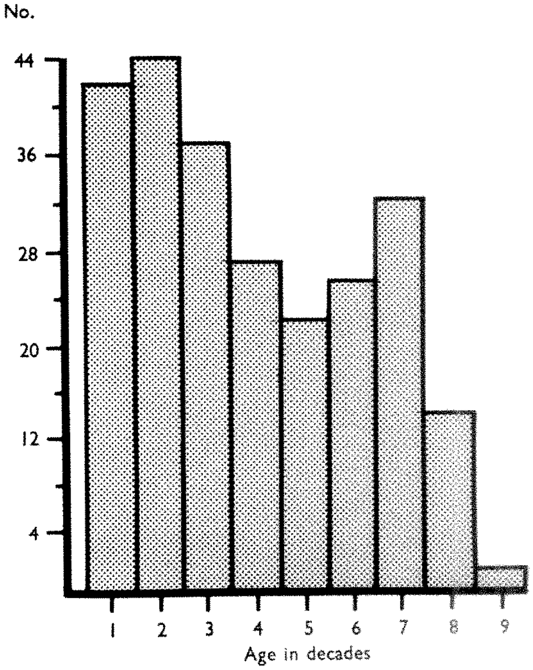

Fig. 1. Age distribution by decade of all cases of head injury admitted to the Mersey Regional Department of Surgical Neurology.

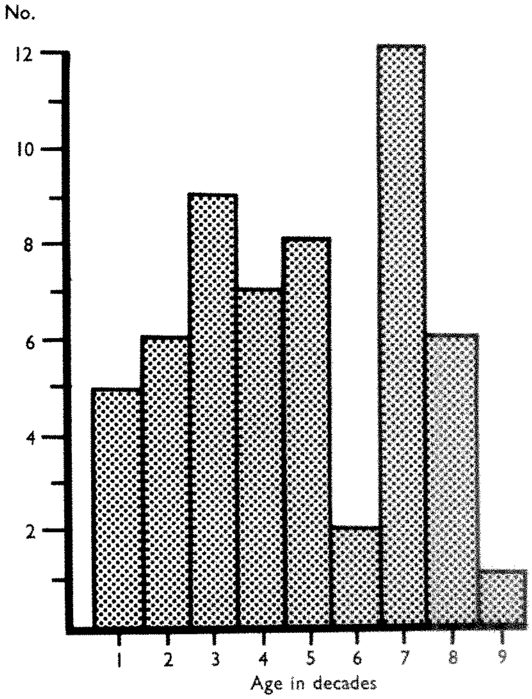

Fig. 2. Age distribution by decade of those dying from a head injury.

major diagnosis has been listed in an attempt to give a rough idea of the relative numbers in the main groups (*Table III*). The group designated 'concussion' comprised those whose period of unconsciousness was in excess of 24 h and was associated with a prolonged post-traumatic amnesia, but who did not develop focal neurological deficit. The group entitled 'other' includes those patients with both depressed levels of consciousness and focal neurological deficit suggestive of either focal or multiple brain contusions and lacerations. Not quite two-thirds (61 per cent) of the patients underwent surgical exploration. Forty-four per cent of patients had an intracranial haematoma, 14 per cent being extradural and 30 per cent subdural.

Clinical outcome

The overall mortality rate was 20 per cent. Twenty-one patients out of a total of 49 were adjudged to be suffering from brain death upon arrival at the neurosurgical unit. Eighteen patients talked and died (Reilly et al., 1975). Analysis of the records and autopsy reports indicates that 14 of these deaths might have been prevented by earlier transfer and treatment. The short term outcome (within 10 days of head injury) is shown in *Table IV* and the long term outcome (more than 6 months after injury) is shown in *Table V*.

Discussion

The age and sex distribution of patients in this series are very similar to figures produced by others (Klonoff and Thompson, 1969; Kerr et al., 1971; *Epidemiology of Head Injuries in England and Wales*, 1976; Jennett et al., 1977). Although road traffic accidents were the major cause of injury in this study, the high incidence of accidents in the home should be noted.

The numbers and outcome in this series must be interpreted against the background of all head injuries within the catchment area. In 1975 and 1976, 226 people died at the scene of the accident, 20 273 patients with head injury were admitted to the district general hospitals and 266 (1·3 per cent) of these died there. In all, 248 patients (1·2 per cent) with severe head injuries were transferred to the Regional Neurosurgical Unit where 19·7 per cent died. It is probable that the majority of patients dying in the district general hospitals had suffered from irreparable brain damage and would not have survived irrespective of treatment. However, some might have been saved. The first 12 h after a severe head injury constitute a particularly critical period and a great deal more study is needed at this level. To this end, a more detailed retrospective study of these 266 patients is at present being undertaken.

It is in the light of these remarks that the mortality rate in different series (*Table VI*) should be viewed. The Mersey Regional Neurosurgical Unit is able to admit only 1·2 per cent of all head injury cases within its catchment area. In the Scottish study the comparable figure for 1974 was nearer 4 per cent (Jennett et al., 1977). Unless the head injuries sustained in Scotland are more severe than those in England and Wales, it seems that there may be some dilution from slightly less severely head injured patients in the Scottish series. This is not to say whether the Scottish transfer ratio is right or wrong. Further study is needed to assess which patients should be transferred to a neurosurgical unit. It is clear, however, that with the numbers of head injuries occurring in the United Kingdom, patients with minor concussion are not likely to be seen by neurosurgeons. However, those dealing with head injuries should be aiming at an ideal whereby any severely injured patient who is deteriorating is transferred immediately. In addition, trial policies—say of transferring all patients who are still unconscious 6 h after the accident—may establish yardsticks that may help improve results.

It is unlikely that any single therapeutic measure is going to make much difference to the outcome. Regimens of treatment and the enthusiasm or otherwise of those surgeons dealing with head-injured patients are probably more important. The two means whereby the mortality/morbidity rate may be reduced are in the areas of accident prevention and the acute treatment in the district general hospitals. As to the former, it should be stressed that in 1975 and 1976 in Merseyside and North Wales, 590 people lost their lives as a result of a head injury.

Patients with head injuries comprised 10 per cent of all patients admitted to the Mersey Regional Department of Surgical Neurology and 75 per cent of emergency admissions. These patients absorb a great deal of time and effort. We are, therefore, encouraged to find that 54 per cent of all such patients resumed their previous occupations but at the same time we recognize that this is a crude criterion by which to judge the true extent of recovery after a major head injury.

It is true to say that there has never been a definitive policy for the treatment of head injuries in the United Kingdom. Policies have evolved locally by varying degrees of liaison between regional neurosurgical centres and district general hospitals depending upon available resources and attitudes of mind. We are disturbed at the number of patients with head injuries dying in the district general hospitals and submit these facts in the hope that they will make a contribution to the very necessary discussions that should take place regarding the management of head injuries in the United Kingdom.

Acknowledgements

The Statistical Department of the Mersey Regional Health Authority and the office of Population Censuses and Surveys very kindly provided the figures for the background information. The cases admitted to the regional unit were under the care of Mr R. H. Hannah, Mr C. B. Sedzimir, Mr J. B. Miles and Mr R. V. Jeffreys. The authors are grateful to them for allowing their case material to be included. We are grateful to Miss L. C. Power for secretarial assistance.

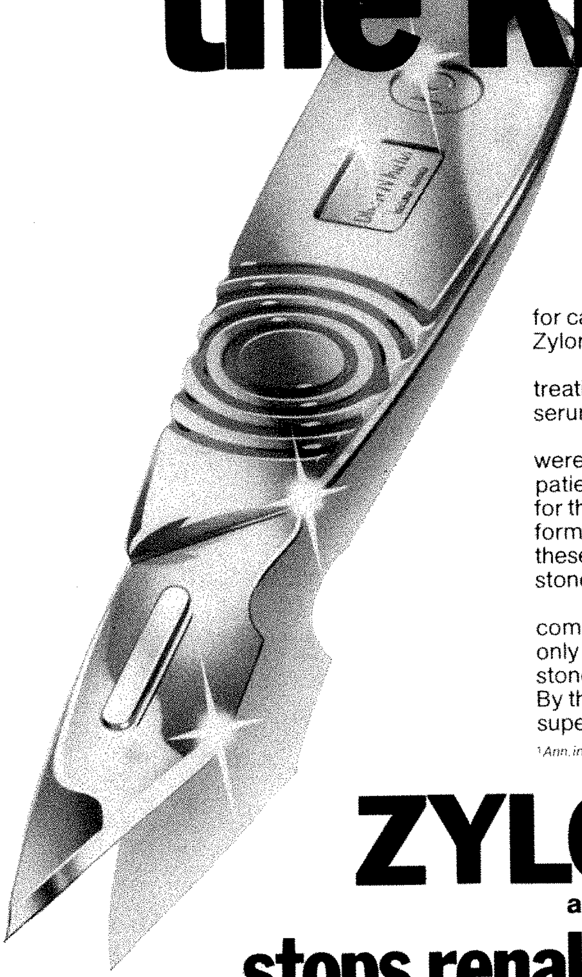
mightier than
the knife



Now there is a practical alternative to surgery for calcium renal lithiasis: long-term prophylaxis with Zyloric.

Zyloric has proved effective in preventing and treating calcium renal lithiasis in patients with raised serum or urinary uric acid.

In a recent trial,[1] 48 patients with hyperuricosuria were treated with Zyloric for an average of 3.88 patient-years. The number of renal stones predicted for this period was 94.9. The actual number of stones formed was 8. Prior to treatment with Zyloric, half of these patients were hospitalised because of stone disease.

A leading article[2] in the *British Medical Journal*, commenting on another clinical paper[3] stated "...the only criterion of success in the treatment of calcium stone disease is total cessation of stone formation. By this criterion, allopurinol (Zyloric) was greatly superior to the placebo."

ZYLORIC-300

allopurinol BP Wellcome

stops renal stones starting

Indications: Conditions of excess body urate including gouty arthritis. Prophylaxis of calcium renal lithiasis in patients with raised serum or urinary uric acid.
Dosage: The average adult dose is one Zyloric-300 tablet daily, plus an anti-inflammatory agent or colchicine for at least one month. Dosage should be adjusted by monitoring serum uric acid until the required level is attained. It has rarely been found necessary to exceed 900 mg per day. Children: 10-20 mg/kg bodyweight/day.
Contra-indications: None, other than known intolerance to Zyloric. **Precautions:** If Puri-Nethol* (6-mercaptopurine) or Imuran* (azathioprine) is given concurrently with Zyloric, the dose of Puri-Nethol or Imuran should be reduced to one quarter of the usual dose. Caution should be observed in pregnancy. Zyloric is not a treatment for acute gout, but prophylactic treatment with Zyloric may be started at the same time as anti-inflammatory treatment. **Side-effects:** These are usually rare and mostly of a minor nature. They include skin reactions, generalised hypersensitivity, gastro-intestinal disorders, blood and lymphatic disorders. **Presentation:** Zyloric-300* is available as 300 mg scored, creamy-white tablets in packs of 28. Basic NHS cost: £5.96 per pack. PL 3/0092. Also available: 100 mg tablets in bottles of 100. Additional information about Zyloric* (allopurinol) is available on request.

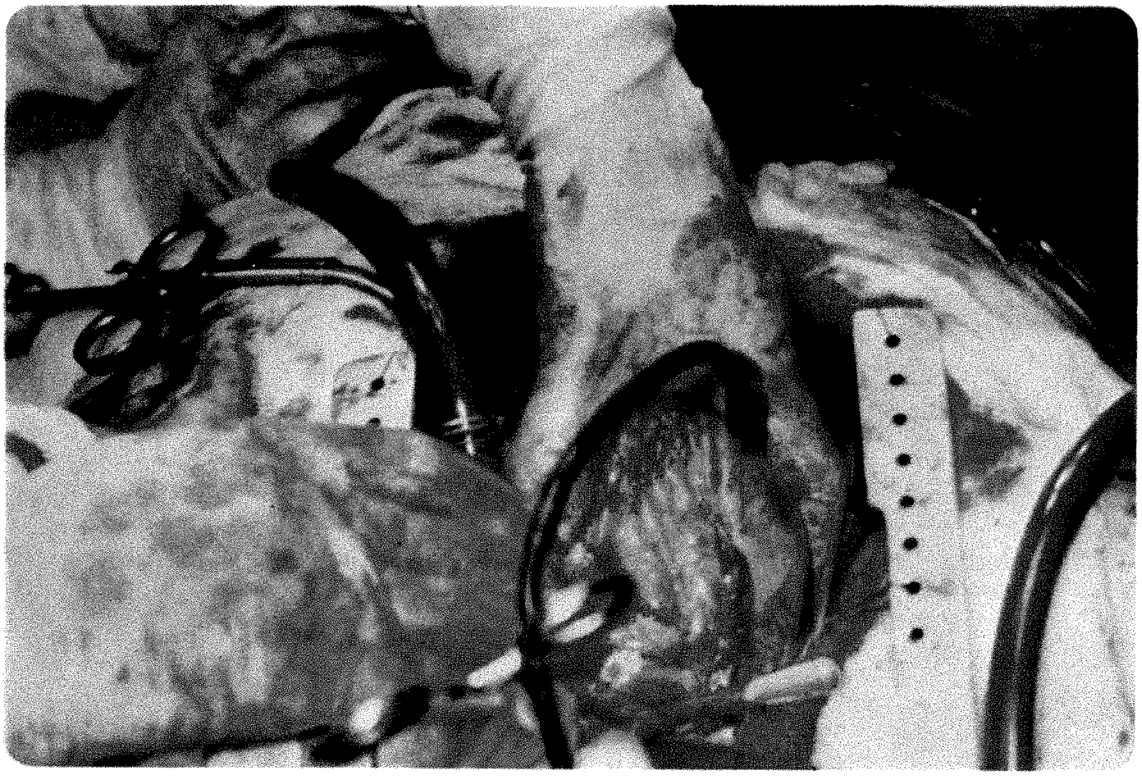
Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted "Magnapen" containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post operative chest and wound infections. Prophylaxis in major surgery.
Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial q.i.d. Children: 2-10 years, ½ adult dose. Under 2 years, ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL0038/5001, 5009
Contra-indications: Penicillin hypersensitivity, ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product literature before using with intravenous fluids.

Basic N.H.S. Prices: (correct at time of printing, Feb 79).
Capsules: 500mg. £18.06 (100 capsule pack).
Syrup: 250 mg per 5 ml. £3.18 (100ml).
Vials: 500mg. £7.45 (10 vials).

Magnapen is available to hospitals on regional contract dependent upon estimated usage.

Further information on Magnapen is available on request to the company.

Magnapen, BRL and the Company logo are registered trade marks.

Experience in the management of 50 consecutive penetrating wounds of the heart

ASHIS K. MANDAL, S. OKPAKO AWARIEFE AND SONNY S. OPARAH*

SUMMARY

Fifty patients with penetrating wounds of the heart were grouped into three categories, based on the clinical severity of the injuries.

Gunshot wounds consistently resulted in a higher mortality than knife wounds. Central venous pressure (CVP) was the single most important means of determining cardiac tamponade. The survival rates in the respective groups were 6, 79 and 100 per cent. The improved survival in our series was due to a rapid transportation system, increased awareness of the significance of cardiac injuries and an aggressive surgical approach.

SINCE Rehn's first successful cardiorrhaphy in 1896 (Balance, 1920), the management of penetrating cardiac injuries has alternated between direct surgical intervention and pericardiocentesis. Disappointed by the high operative mortality of 50 per cent, Blalock and Ravitch in 1943 advocated non-operative treatment of selected cases of cardiac wounds. This approach to therapy has also been advocated by others (Isaacs, 1959; Beall et al., 1961). In recent years, the trend has shifted to more aggressive treatment (Yao et al., 1968; Borja et al., 1970; Beall et al., 1972; Anagnostopoulos and Kittle, 1973; Bolanowski et al., 1973; Rasaretnam and Paul, 1974; Maynard et al., 1975). Despite early surgical intervention, the mortality rate remains inordinately high. The purpose of this retrospective study is to evaluate the factors that influence the survival rate.

Patients and methods

This retrospective study comprised 50 consecutive cases of penetrating injury of the heart treated at Martin Luther King Jr General Hospital from March 1972 to March 1978. There were 30 stab wounds and 20 gunshot wounds. Forty-six of the patients were men and 4 women. Their ages ranged from 12 to 53 years with a mean of 26 years. These patients were divided into three clinical groups as suggested by Steichen et al. (1971). Group A consisted of 18 'lifeless' patients who were received without blood pressure, pulse or respiration and the pupils were usually fixed and dilated. Seven (39 per cent) of these had stab wounds and 11 (61 per cent) had gunshot wounds (*Table I.*) All the patients required immediate thoracotomy. Group B consisted of 24 patients who underwent urgent thoracotomy. These patients were admitted in varying degrees of shock and cardiac tamponade. Seventeen (71 per cent) of these had stab wounds and 7 (29 per cent) had gunshot wounds. Group C comprised 8 patients who were received in a stable, normotensive state, 6 (75 per cent) of them having sustained stab wounds and 2 (25 per cent) gunshot wounds. The only evidence suggestive of cardiac injury in this group of patients was the presence of precordial wounds with elevated central venous pressure and/or electrocardiographic changes.

Table I: CLINICAL CLASSIFICATION IN CORRELATION WITH TYPE OF INJURY

Group	Stab wounds	Gunshot wounds	Total
A	7 (39)	11 (61)	18 (36)
B	17 (71)	7 (29)	24 (48)
C	6 (75)	2 (25)	8 (16)
Total	30 (60)	20 (40)	50 (100)

Figures in parentheses are percentages.

Management

All patients arrived in the emergency room within 1 h of the injury. They were initially treated in the critical room, which is a specially designated area of the emergency room equipped with facilities for emergency surgical procedures. Patients in groups A and B were immediately intubated and received assisted ventilation. Simultaneously, at least three intravenous lines were inserted using large bore needles (no. 16 gauge). One of these lines was a percutaneous central venous line. Blood was drawn for grouping and cross-matching, complete blood count and estimation of electrolytes and arterial blood gases. A Foley catheter was inserted and an electrocardiogram obtained. Hypovolaemia was initially treated with lactated Ringer's solution, 5 per cent albumin and O-negative blood until cross-matched blood was available. Haemothorax or haemopneumothorax if present was treated by tube thoracostomy with water-seal drainage. Two thousand five hundred units of heparin were added to the drainage bottle in case there was need for autotransfusion (Mattox et al., 1975; Koch et al., 1977).

Group A patients underwent immediate thoracotomy in the emergency room for pericardiotomy to relieve cardiac tamponade and to perform manual cardiac massage and myocardiorrhaphy. Other injuries were repaired in the main operating theatre.

In group B, 12 of the 17 stab wound cases and 3 of the 7 gunshot wounds had clinical evidence of cardiac tamponade with a CVP greater than 14 cmH_2O and hypotension. Two patients with stab wounds had blood pressures greater than 100 mmHg systolic with CVPs greater then 30 mmH_2O. All 15 patients with the clinical evidence of cardiac tamponade underwent pericardiocentesis via the left xiphicostal angle. The amount of blood obtained from pericardiocentesis varied from 10 to 150 ml.

The indications for thoracotomy were the presence of a precordial wound, thoracic or extrathoracic injuries from high velocity missiles which are likely to injure the heart, distended neck veins and an elevated CVP or low CVP in the face of hypovolaemia. The average time interval between arrival in the emergency room and thoracotomy was 45 min. All except 2 patients underwent anterolateral thoracotomy, the remaining 2 having a median sternotomy. Cardiopulmonary bypass was required in only 2 patients. Active bleeding from a cardiac chamber was controlled by local pressure with a finger. Occasionally the bleeding was controlled with the help of a 20 F Foley catheter which was introduced into the heart through the wound, the balloon was inflated and traction applied to the catheter so that the balloon occluded the leaking wound in the cardiac wall. The cardiac wound was repaired with non-absorbable 2/0 or 3/0 sutures in horizontal mattress stitches or 'U' horizontal mattress stitches to avoid injury of the coronary arteries. Teflon or tissue pledgets were used to buttress the stitches. In cases of very active bleeding, finger compression of the base of the heart through the transverse sinus was required to slow down bleeding in order to facilitate

suturing (Beck, 1926). Atrial wounds were controlled with vascular clamps before repair.

Group C patients had electrocardiogram changes suggestive of myocardial injury in 4 of 6 stab wound cases and 1 of 2 gunshot wounds. The only patient in this group who later required thoracotomy had sustained a stab wound to the fourth left intercostal space in the midclavicular line. He was initially normotensive with normal CVP. Following 5 days of close observation the patient was discharged but was readmitted 3 weeks later with persistent chest pain and dyspnoea on exertion. The CVP at this time was elevated and pericardiocentesis produced 350 ml of serosanguineous fluid. At thoracotomy only blood clot and fibrin were found within the pericardium. Five out of 8 patients in this group required tube thoracostomy for haemothorax or haemopneumothorax.

The most frequently presenting sign in patients in groups B and C (32 patients) was distended neck veins with a CVP greater than 14 cmH_2O this was noted in 22 cases (69 per cent). The second most frequent finding was hypotension in 20 (63 per cent). Muffled heart sounds and electrocardiogram abnormality were each noted in 19 cases (59 per cent). Dyspnoea/cyanosis and cardiomegaly on a chest radiograph were the least frequently noted findings and least reliable signs of cardiac injury. The presence or absence of pulsus parodoxus was not recorded (*Table II*).

Results

Among the patients who underwent thoracotomy, one or more cardiac chambers were involved in 38 patients. Twenty-three (61 per cent) of these cases involved the left ventricle with a mortality of 52 per cent. The right ventricle was involved in 13 (34 per cent) with a 46 per cent mortality. The left atrium was involved in only one case who survived and the right atrium was involved in 9 patients with 89 per cent mortality. Multiple chamber involvement was present in most cases. In patients who had only one cardiac chamber involved the mortality rate was 29 per cent whereas in those with multiple injuries the mortality rate rose correspondingly (*Table III*).

Associated injuries were more frequent in group A. There was a variety of intrapericardial injuries, such as injury to the coronary arteries, aorta and pulmonary trunk and traumatic ventricular septal defect, and in each such patient the mortality was 100 per cent. There were also superior vena cava, azygos vein and extrapericardial aortic injuries in group A. These associated injuries were more frequent in cases with gunshot injuries than in those with stab wounds. There was a consistently higher survival rate among the stab wound cases than the gunshot wounds (*Table IV*). The survival rate in group A for patients with stab wounds and gunshot wounds was 14 and 0 per cent respectively while that of group B patients was 94 and 43 per cent respectively. All the patients in group B survived. When both stab wounds and gunshot wounds were combined the survival rate for groups A, B and C were 7, 79 and 100 per cent respectively.

Discussion

With the easy availability of hand guns the incidence of trauma due to high velocity missiles has increased significantly (Beall et al., 1972; Carrasquilla et al., 1972; Symbas et al., 1976; Szentpetery and Lower, 1977). Martin Luther King Jr General Hospital is located in South Central Los Angeles where homicide is one of the major causes of death (Haynes et al., 1973; Mandal et al., 1976). During the period under study, a total of 611 patients with penetrating chest injuries received treatment and 50 (8 per cent) of these patients sustained penetrating cardiac wounds. This is in contrast to the report of Siemens et al. (1977), who found an incidence of 16 per cent. In this series of 50 penetrating cardiac injuries, 35 per cent of the cases were categorized as 'lifeless' (Group A). Ordinarily these cases would have been pronounced dead at the scene of injury or dead on arrival in the emergency room but because of our policy of aggressive management 9 out of these 18 'lifeless' patients (50 per cent) responded to initial surgical therapy with return of normal cardiac activity following myocardiorrhaphy and manual cardiac massage, but 8 of these subsequently died of irreversible shock. The fact that we have been able to salvage one patient is a strong testimonial to the beneficial effects of immediate thoracotomy in this type of case. Mattox et al. (1974) reported 100 per cent mortality in 11 such 'lifeless' patients out of 48 who were treated for penetrating cardiac injuries. Other reported mortality rates have varied from 50 to 67 per cent (Steichen et al., 1971; Symbas et al., 1976) (*Table V*).

Cardiac tamponade is the most important life endangering complication of penetrating cardiac wounds (Martin and Schenk, 1960; Beall et al., 1961). Sixty-nine per cent of our patients exhibited clinical signs of cardiac tamponade: this is consistent with the findings of Martin and Schenk (1960). Pericardiocentesis for the relief of tamponade is imperative as the temporizing measure that offers the best chance of survival.

The pathophysiological consequences of cardiac tamponade have been well described (Cohnheim, 1889; Starling, 1897; Metcalf et al., 1952; Isaacs et al., 1954; Martin and Schenk, 1960; Carey et al., 1967; Spodich, 1967; Poris and Gaudiani, 1975). In 1889, Cohnheim postulated that the cause of circulatory impairment in cardiac tamponade was the obstruction at the veno-atrial junction, while Starling in 1897 attributed this problem to impairment of diastolic expansion. It is now widely accepted that the diminished effective filling pressure and the mechanical limitations of the right ventricular filling are the primary mechanisms responsible for the decreased cardiac output seen in acute cardiac tamponade (Martin and Schenk, 1960; Carey et al., 1967; Spodich, 1967; Poris and Gaudiani, 1975). By increasing plasma volume one may hope to improve cardiac output (Metcalf et al., 1952; Martin and Schenk, 1960; Poris and Gaudiani, 1975). We found elevation of the CVP to be the most reliable criterion for the presence of cardiac tamponade. This concurs with the findings of other investigators (Martin and Schenk, 1960; Beall et al., 1966; Yao et al., 1968; Symbas et al., 1976). Of 32 patients who were checked for CVP elevation, 22 (69 per cent) had pressure readings of 14 cmH_2O or higher and 18 of these (82 per cent) had productive pericardiocentesis. After aspiration of as little as 10 ml of non-clotting blood from the pericardial space, patients showed dramatic improvement. Other reports confirm this response (Beall et al., 1961; Levitsky et al., 1975). A non-productive pericardiocentesis does not rule out tamponade. Four patients who had unproductive pericardial aspiration had pericardial blood clots at thoracotomy. During rapid bleeding into the pericardial space, the possibility of clot formation is much greater than during slow bleeding because of inadequate agitation of the blood by the heart during the rapid bleeding (Ransdell and Glass, 1960). Borja and co-workers (1970) have reported that up to 25 per cent of patients with documented tamponade have had non-productive pericardial aspiration.

Absence of CVP elevation does not rule out cardiac injury. In the presence of hypovolaemia the CVP may be extremely low (Neville et al., 1971; Symbas et al., 1976; Szentpetery and Lower, 1977). A normal cardiac silhouette on a chest radiograph does not rule out tamponade either, for several millilitres of blood may be present in the pericardial space and yet it may not be radiographically obvious. It is the rapidity with which the fluid accumulates and not the amount of fluid that determines how rapidly cardiac tamponade is manifested (Bolanowski et al., 1973; Szentpetery and Lower, 1977). Muffled heart sounds were also found to be equally unreliable in assessing the presence of cardiac tamponade, as were electrocardiogram changes, which were present in only 59 per cent of our patients.

Since the pathophysiological manifestations of penetrating injuries are largely dependent on the extent of the injuries, which in turn relates to the wounding agent (Levitsky, 1975), it follows that stab wounds result in lower mortality. Such was the case in this study. Except in group C, there was a consistently high mortality rate from gunshot wounds. As noted by Jones and Helmsworth (1968), this was attributed to the velocity of the missile, extent of the wound, number of holes in the heart, exsanguination, intracardiac defects and other associated injuries. As a result of the larger holes produced by bullets there is a tendency for the pericardial wounds to remain open, allowing free drainage of the pericardial blood into the thoracic cavity. Such patients present with signs and symptoms of haemorrhage, haemothorax and hypovolaemic shock rather than tamponade (Martin et al., 1960; Szentpetery and Lower, 1977).

In group B the overall mortality was 21 per cent. Several factors seem to be responsible for such low mortality. There were twice as many stab wounds as gunshot wounds in this group, in contrast to group A. These patients were brought to the emergency room at a relatively early stage and were managed by an early thoracotomy. Beall and co-workers (1966) showed that when thoracotomy was performed without delay in patients with tamponade there was a 14·6 per cent mortality whereas when cardiac arrest was allowed to set in, the mortality rose to 60 per cent. Stab wounds may seal spontaneously following the egress of a small amount of blood into the pericardial sac (Levitsky, 1975). Wounds of the atrium may produce relatively slow haemorrhage with slow development of tamponade such that the patients are able to live longer while being transported to the hospital (Jones and Helmsworth, 1968). At the turn of the century it was thought that wounds of the auricle were more fatal than those of the ventricle because of the thinness of the wall, which resulted in less tendency to close. For similar reasons, right ventricular wounds were believed to bleed continuously while left ventricular wounds were thought to bleed intermittently (Neville et al., 1971). In our series, the ventricular chambers were frequently involved regardless of the type of injury; similar findings have been noted by others (Lemos et al., 1976; Asfan and Arbulu, 1977). In a report of 323 cases of penetrating wounds of the pericardium and heart, Asfan and Arbulu found that stab wounds of the right ventricle were more frequently associated with tamponade than wounds of the left ventricle (Asfan and Arbulu, 1977). Wounds of the thick muscular ventricular myocardium also frequently presented with a large volume of pericardial fluid

(Metcalf et al., 1952; Jones and Helmsworth, 1968). Such patients showed dramatic improvement following pericardiocentesis and subsequently remained remarkably stable. Small wounds that were once occluded by clot may open up during systole when the clot is expressed (Von Berg et al., 1961). Recurrent cardiac tamponade after pericardiocentesis killed 10 of 18 patients reported by Sugg et al. (1968).

The right ventricle has been reported as being the most frequent site of injury (Jones and Helmsworth, 1968; Sugg et al., 1968; Mattox et al., 1974; Symbas et al., 1976). According to the report of Jones and Helmsworth (1968), anatomical locations of cardiac injuries were 58 per cent in the right ventricle, 20 per cent in the left ventricle and 10 per cent in the right atrium. The rationale given for this distribution is the geometry of the heart in relation to the anterior chest wall. Our study does not substantiate this finding: out of a total of 38 cases in our series in which cardiac chambers were involved, the left ventricle was affected in 61 per cent, the right ventricle in 34 per cent, the right atrium in 24 per cent and the left atrium in 3 per cent. This change in frequency of involvement of various chambers of the heart in our series compared with the reports in the literature is perhaps due to an increased incidence of gunshot injuries in the population served by our hospital. In our series the highest death rate (89 per cent) was noted in patients who had right atrial involvement. This is consistent with the reports in the literature (Neville et al., 1971). Rasaretnam, however, has reported a higher mortality with left ventricular injuries (Rasaretnam and Paul, 1974). The mortality rate is high in group A regardless of the type of injury. With an increasing trend towards early thoracotomy the mortality rate for all types of penetrating cardiac injury seems to be decreasing.

Percutaneous transhepatic occlusion for bleeding oesophageal varices

J. M. HENDERSON, T. A. S. BUIST AND A. I. S. MACPHERSON*

SUMMARY

Using the technique described by Lunderquist et al. (1977), transhepatic injection of oesophageal varices has been performed under local anaesthesia in 9 patients with portal hypertension (11 procedures). On 2 occasions it was not possible to enter the left gastric vein. Bleeding resumed within 2 days of radiologically satisfactory occlusion in 2 patients and at 1, 3, 4 and 10 months after 4 procedures in 3 patients. Other complications included portal vein thrombosis, gross ascites and right pleural effusion. There were 2 hospital deaths, both in alcoholic patients with poor hepatic function. In spite of the apparently high morbidity we consider that there is a place for this technique in tiding over patients who are bleeding from oesophageal varices and are medically unsuitable for any surgical procedure.

ADEQUATE blood transfusion, pitressin and tamponade by a double-balloon tube control most acute episodes of bleeding from oesophageal varices and allow time for full assessment and definitive treatment. Early decompression by emergency shunt as advocated by Orloff et al. (1975) is not widely practised, most clinicians preferring early elective operation in those selected as suitable following control of bleeding and full assessment (Macpherson, 1964). Two further methods of controlling bleeding which have been practised are direct injection of the varices through a rigid oesophagoscope (Johnston and Rodgers, 1973) and transhepatic occlusion, as advocated by Lunderquist and Vang (1974). We report our preliminary experience with this latter technique with particular reference to the early complications.

Patients and methods

Patients

Nine patients were treated (*Table I*): there were 7 men and 2 women with an age range from 32 to 71 years. In all but 1 patient (*Case* 6) the indication for the procedure was recurrent bleeding despite adequate conservative management. This patient had had a previous lieno–renal shunt but had persistent large varices and the indications for the procedure were diagnostic and prophylactic rather than therapeutic. All the patients had cirrhosis, 4 presumed or proved alcoholic, 4 of unknown aetiology and 1 post-hepatitic. The grade of the liver disease is shown in *Table I* according to Child's classification, considering ascites, encephalopathy, serum bilirubin and albumin and the prothrombin time ratio. The blood transfusion requirement of each patient is given as an indication of the severity of the bleeding.

In 2 of the 9 patients (*Cases* 3 and 4) the procedure had to be repeated, in both instances for further bleeding at 17 and 4 weeks respectively. Thus, 11 procedures were performed in all.

Method

The procedure was carried out in the X-ray department with image-intensified fluoroscopic control. The position and patency of the portal vein were first established by selective coeliac and mesenteric arteriography. Percutaneous transhepatic catheterization of the portal vein was performed through the right eighth or ninth rib interspace in the mid-axillary line under basal sedation (diazepam) and local anaesthesia. Using a technique similar to that described by Lunderquist et al. (1977), a catheter (6 FG) introduced over a matching needle was passed through the liver into a large intrahepatic branch of the portal vein. In most cases this was entered after three or four passes, care being taken that the needle was not withdrawn from the substance of the liver. The needle was then withdrawn and a flexible guide wire passed through the catheter which was manipulated down the portal vein and into the splenic vein. Portal venous pressure was measured and contrast medium injected while serial films were exposed to demonstrate the portal venous system, the varices and their principal feeding vessels and other collaterals (*Fig.* 1). The main sources of supply to oesophageal and gastric varices are the left gastric vein and the short gastric veins. A pre-curved guide wire was used to position the catheter within the left gastric vein and contrast medium injected there confirmed filling of the varices from this vessel (*Fig.* 2). Occlusion of this vessel was achieved by embolization with absorbable gelatin sponge (Sterispon) (*Fig.* 3). In later patients the gelatin sponge was soaked in a sclerosant, sodium tetradecyl sulphate (STD), to induce a longer-lasting venous occlusion (Viamonte et al., 1977). Other enlarged branches of the splenic vein supplying varices can be occluded by the same method. During withdrawal of the catheter, the track through the liver was occluded

Table I: PATIENTS STUDIED

Case no.	Age (yr)	Sex	Aetiology of liver disease	Grade of liver disease	Blood transfused
1	48	M	Alcohol	B	6 l
2	32	M	Alcohol	B	8·5 l
3	52	M	Alcohol	C	8 l
4	71	M	Cryptogenic	B	4·5 l
5	69	F	Cryptogenic	B	10·5 l
6	51	M	Post-hepatitis	A	0
7	48	M	Cryptogenic	B	3·5 l
8	41	M	Alcohol	B	9 l
9	60	F	Cryptogenic	B	4 l

Table II: RESULTS

Case no.	Occlusion	Recurrent bleeding	Ascites	Pleural effusion	Outcome
1	Satisfactory	2 d			OT
2	Satisfactory		++	++	Died 5 d
3	Satisfactory	4 mth			PVT
	Unchanged				Well 11 mth
4	Satisfactory	1 mth	+	+	
	Unchanged	10 mth			OT
5	Satisfactory				Well 14 mth

with further plugs of gelatin sponge to minimize the risk of bleeding from the hepatic puncture.

Results

Satisfactory occlusion of the principal feeding vessels was achieved in 8 of the 11 procedures (*Table II*). In 7 instances this occlusion was confined to the left gastric vein and in the eighth procedure, which was a second embolization, the short gastric veins were occluded. The reasons for the 3 failures were portal venous thrombosis preventing catheterization at the second procedure in *Case* 3, inability to catheterize selectively the left gastric vein in *Case* 6 due to its acute angle of entry (probably a consequence of previous surgery) and inability to advance the catheter down the portal vein, despite its patency as shown by preliminary arteriography, in *Case* 7. In this patient ascites sufficient to separate the liver from the abdominal wall contributed to the difficulty in catheter manipulation.

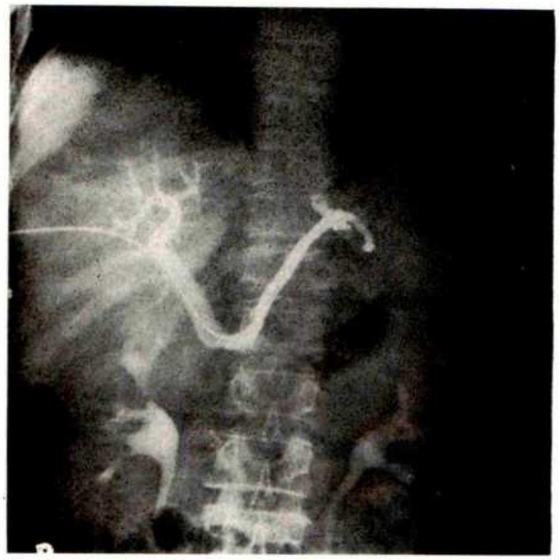

Fig. 3. Occlusion of left gastric vein.

Recurrent bleeding

Five patients bled again, 2 dramatically in the first 48 h after apparently satisfactory occlusion of the left gastric vein and 3 after a longer interval. Four patients, including the 2 early recurrences, came to surgery, 3 to oesophageal transection and 1 to a transgastric ligation. The other 2 had repeat procedures. *Case* 3 was found to have a portal venous thrombosis 17 weeks after the first injection. This precluded further occlusive measures, but the patient has not bled since. In *Case* 4 a further successful occlusion was achieved but bleeding recurred 9 months later.

Ascites and pleural effusion

There was a noticeable increase in ascites following 5 procedures in 4 patients in whom it was already present and in 3 of these patients there also developed a massive right pleural effusion. In one other patient (*Case* 3) a right pleural effusion developed without any clinical change in the ascites.

Mortality

There were 2 deaths, *Case* 2 already mentioned and *Case* 8 who bled again within 24 h and required ligation of a bleeding gastric varix. He died 16 days later from progressive hepatic failure.

Of the other 7 patients, 3 have subsequently had oesophageal transection for recurrent bleeding at 48 h, 12 weeks and 10 months respectively. All are alive 3–14 months after the transhepatic injection.

Discussion

Reported experience with transhepatic injection of oesophageal varices from other centres has shown that an occlusion rate of the order of 90 per cent can be achieved (Scott et al., 1976; Lunderquist et al., 1977; Viamonte et al., 1977) with a hospital mortality rate of 18 per cent. The incidence of recurrent bleeding in those in whom occlusion has been obtained is collectively reported as 20 per cent. Our results have been less satisfactory, 6 episodes of recurrent bleeding having occurred in 5 of the 9 patients, 2 within 48 h of the procedure and 4 at 1, 3, 4 and 10 months afterwards.

The early complications of increasing ascites and right pleural effusions, which have been significant problems in our experience, have not been reported elsewhere. Scott and his colleagues (1976) reported 5 of their 13 patients as having a right haemothorax following the procedure, but none of the other reports mention pulmonary complications. The effusions we have encountered have not been bloodstained, and there was no evidence of significant bleeding from the hepatic puncture sites. The two complications of increase in an already present ascites and the development of a right pleural effusion appear to be intimately connected. The tendency to fluid accumulation in these ill patients and the reaction of the serous membranes to the passage of the needle may be sufficient explanation of the coincidental appearance of these complications. Occlusion of portasystemic connections through the left gastric vein could lead to a temporary increase in portal venous pressure and thereby to an increased tendency to ascitic fluid formation. During hepatic puncture the pleural cavity may be traversed by the needle and cannula and a direct pleuroperitoneal communication established through which, though of small size, ascitic fluid under pressure could leak. This sequence appeared to occur in *Case* 2, who had a satisfactory occlusion and developed a very tense ascites and a rapidly accumulating right pleural effusion which undoubtedly contributed to his death. We consider that a significant degree of ascites is a contraindication to this procedure.

Manipulation of the guide wire and catheter and several injections of contrast medium probably increase the risk of portal vein thrombosis, particularly if the blood flow in that vessel is already slowed. However, this complication has not previously been reported. Lunderquist and his colleagues (1977) in an addendum to their report comment on marginal thrombus being found in the portal vein at necropsy in some of their patients, but point out that this is a common finding in this group anyway. Our *Case* 3 was found to have portal vein thrombosis at repeat examination at 4 months, this being confirmed at splenoportography, and we believe that this must be recorded as a complication of the technique.

The incidence of recanalization of occluded vessels varies widely from series to series. Early workers employed substances such as 50 per cent glucose and thrombin (Lunderquist et al., 1977), and in patients in whom occlusion was undertaken with these substances recanalization was common. Viamonte and his colleagues (1977) found that none of 10 patients occluded with Gelfoam and STD had recanalized when reassessed. Attempts at more permanent occlusion with Bucrylate (isobutyl-2-cyanoacrylate) have been reported (Rosch et al., 1975; Lunderquist et al., 1977), but follow-up reports are still awaited. Only 3 of our patients have had radiological reassessment, and none had recanalized the occluded vessels in the short term. In one case who came to necropsy complete occlusion of the left gastric vein was confirmed.

Despite the complications we have encountered, we believe that transhepatic injection of oesophageal varices is a useful additional therapeutic technique in the management of the bleeding patient with portal hypertension. Its principal advantage is that it does not require general anaesthesia and therefore can be employed in the seriously ill patient who has continued to bleed despite adequate conservative treatment. The relief it provides should be looked on as temporary for only the main feeder veins are occluded and, as with transoesophageal injection or ligation of varices, it should be followed by definitive surgery when circumstances permit. Significant ascites is, in our opinion, a contraindication to the procedure.

Pyloric diaphragm, antral web, congenital antral membrane—a surgical rarity?

K. G. MITCHELL, A. MCGOWAN, D. C. SMITH AND G. GILLESPIE*

SUMMARY

Three cases of pyloric diaphragm in elderly patients are reported. The finding of these patients within a 2-year period (1976–8) suggests that the condition is not as rare as previously thought. Diagnosis was achieved endoscopically and the condition managed surgically.

While there has been controversy in the past over whether the disorder is acquired or congenital, the histological evidence of the cases presented here tends to suggest that it is a late presentation of a congenital abnormality.

MOST instances of pyloric obstruction in the adult are either due to stenosis from duodenal ulceration or to carcinoma. Obstruction from a congenital pyloric diaphragm (*Fig.* 1) has been reported but has been recognized by endoscopy on only a few occasions.

We report here 3 cases of pyloric diaphragm presenting for the first time in late adult life.

Case reports

Case 1: J. McR., a female aged 70 years, presented in March 1978 with a 6-month history of anorexia, occasional vomiting and weight loss. There was no history of pain, heartburn or water brash. Her past medical history was unremarkable.

The initial barium meal examination showed a grossly dilated stomach with a large food residue. A presumptive diagnosis of pyloric stenosis was made. In view of the relative lack of symptoms and absence of a previous dyspeptic history, surgical intervention was deferred and a second barium meal examination, 3 months later, suggested a pyloric diaphragm.

Two endoscopic examinations were made; the first failed to demonstrate patency of the pylorus and the second showed a smooth pinhole pyloric opening.

At laparotomy, a duodenotomy was performed and the examining finger, passed proximally, could not negotiate an antral obstruction. The duodenum itself was normal. Gastrotomy revealed a smooth antral diaphragm with a 2-mm centrally placed os through which a fine probe was passed. Antrectomy with gastroduodenal anastomosis was performed. Six months after surgery the patient remains well.

The resected specimen consisted of a portion of gastric antrum, including the pylorus, with an attached cuff of duodenum. The normal pylorus was recognized by its characteristic mucosal folds and serosal groove. A diaphragm, complete apart from a central 1–2-mm orifice, was located 1·5 cm proximal to the pylorus. The stomach wall was rather thickened proximal to the diaphragm and the gastric mucosa flattened with a pebbled appearance. There was no ulceration in either the stomach or the duodenum. Histology of the diaphragm showed a central core of submucosa covered on both proximal and distal aspects by normal gastric mucosa. These appearances are consistent with an antral diaphragm.

Case 2: M. L., a female age 77 years, presented in April 1978 with a short history of general malaise and vomiting after meals. She was pain-free, had a good appetite and her weight was steady. A barium meal examination demonstrated pyloric hold-up. Endoscopy showed a small histus hernia with an area of lower oesophageal ulceration. The gastric mucosa appeared normal but the pyloric opening was only the size of a pinhole, smooth and impossible to negotiate (*Fig.* 2). A diagnosis of a pyloric diaphragm was made.

Laparotomy revealed findings similar to those in *Case* 1. Antrectomy with gastroduodenal anastomosis was performed. The patient remains well 6 months after surgery.

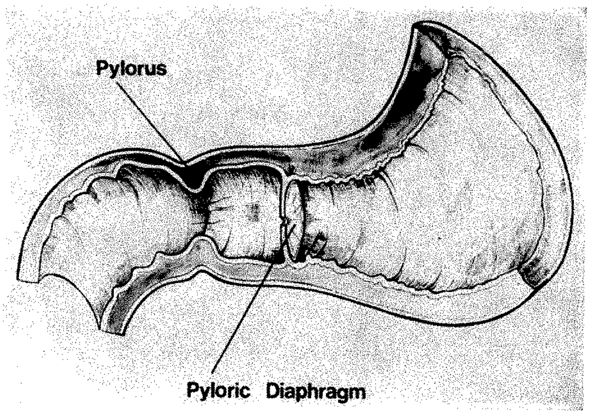

Fig. 1. Artist's impression of pyloric diaphragm.

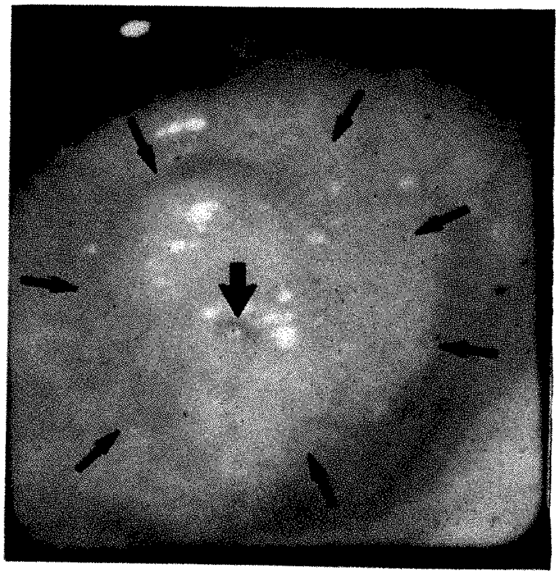

Fig. 2. Endoscopic photograph (*Case* 2) showing pinhole aperture in diaphragm (central arrow). The periphery of the diaphragm is shown (ring of arrows), peristalsis ceasing here.

The surgical specimen was essentially the same as in *Case* 1 except that the diaphragm was in the vicinity of the pylorus, which could not be separately identified. The presence of Brunner's glands in sections taken just distal to the diaphragm suggested that this was a pyloric diaphragm. There was no evidence of recent or past ulceration in either the stomach or the duodenum. Some hypertrophy of the gastric musculature was evident.

Case 3: J. G., a female aged 71 years, presented in November 1976 with a 40-year history of epigastric discomfort which has

---

Correspondence to: G. Gillespie.

been treated as peptic ulceration with little relief. During the year before presentation, the pain became more severe, particularly following meals. The patient was nauseous but had never vomited.

Barium meal examination was reported as showing no evidence of peptic ulceration, but narrowing of the pylorus suggestive of a pyloric diaphragm. This was confirmed at endoscopy when a pinhole pylorus was found through which the endoscope could not be passed.

At laparotomy an advanced carcinoma of the body of the pancreas was found. The stomach was not examined. The patient died 5 weeks later.

Discussion

Congenital malformations of the stomach are exceedingly rare. Parrish et al. (1966) estimated the incidence as 1 in 1 000 000 births. Since Sames (1949) described partial atresia of the pyloric antrum due to a mucosal diaphragm, over 50 similar cases have been described (Sloop and Montague, 1967; McBee and North, 1970; Javier-Gabriel, 1976). The true incidence of this condition is difficult to assess because of differences in nomenclature (Schwartz et al., 1977), variations in classification and the wide age distribution.

Recognition of the lesion was simplified by Gerber and Aberdeen in 1965. They reviewed the literature and suggested the lesion be classified as follows:

I. Pyloric: (A) membrane; (B) atresia.

II. Antral (1 cm or more proximal to the pylorus): (A) membrane; (B) atresia.

Pyloric and antral atresias (IB and IIB) present in neonates but are much less common than duodenal atresias, and a review by Ghent and Denton in 1974 revealed only 6 cases of pyloric atresia and 11 cases of antral atresia. Both pyloric and antral membranes (IA and IIA) occur over a wide age spectrum with peak incidences in infancy and the seventh decade (Munro, 1963; Banks et al., 1967). The incidence in this series is similar to that of the Mayo Clinic, reported by Feliciano and van Heerden in 1977, in which 7 cases occurred over a 5-year period. An even greater incidence of 4–5 per year was quoted by Tanner (1967). However, Rowling (1959) failed to identify a single case in 2625 autopsy studies.

Most authors favour a congenital aetiology with failure of gut canalization in the 5th–6th embryonic week as the most likely explanation. Others suggest fetal injury with subsequent damage to the affected part (Bell et al., 1977). However, the late onset of symptoms creates doubts as to whether in fact the lesion is congenital or not. Rhind (1959), Strange (1967) and van der Reis et al. (1977), postulated an inflammatory aetiology and suggested that the lesion was due to scarring from annular ulceration of the pylorus. However, the mild inflammatory changes, such as those in *Case* 1, are generally regarded as secondary to stasis, and the uniformity of the histological appearances, with which *Cases* 1 and 2 accord, is in favour of a congenital origin.

Why a congenital condition should take 50 years to produce symptoms is difficult to explain (Dorch et al., 1976). Some suggest that those cases that present late in life are associated with edentulous mastication and indeed one case presented soon after removal of all the patient's teeth (Passalacqua and Romero, 1955). A further theory postulates that with advancing age there is a general decrease in tone in an already hypertrophied stomach (Swartz and Shepherd, 1956; Hait et al., 1972).

The clinical and laboratory findings are similar to those found in pyloric stenosis.

Barium studies frequently provide a diagnosis of pyloric obstruction, but unless the characteristic knife-like linear defect in the antrum or the appearance of a double duodenal bulb are seen, the actual cause of the pyloric obstruction cannot be clarified. Indeed, the opening in the diaphragm can easily be mistaken for the pylorus itself. Concentrated barium may obscure the signs and for this reason careful technique and double-contrast studies are advisable.

Gastroscopy was performed in all 3 cases in this series and a correct diagnosis made. The findings of a dilated stomach with a small, fixed antral aperture, normal gastric mucosa and peristalsis ceasing abruptly at the margins of the membrane fulfil the diagnostic criteria laid down by Sokol et al. (1965) and Banks and Waye (1969).

Management of this condition is surgical. Simple incision of the diaphragm has been reported (Conway, 1965). Similarly, excision of the diaphragm at its junction with the stomach wall appears to give satisfactory results (Robinson, 1967). In our series, antrectomy proved a satisfactory surgical treatment and additionally allowed full histological examination. Drainage procedures with or without vagotomy have less favourable results and simple stretching of the aperture has proved difficult (Katz, 1968; Johnson, 1971). The value of a preliminary exploratory gastrotomy or duodenotomy has been emphasized (Parrish et al., 1968).

With the advent of endoscopic diathermy techniques it may soon be possible to incise the diaphragm without resorting to laparotomy (Javier-Gabriel, 1976).

Gastric volvulus following highly selective vagotomy: a case report

S. P. KAUSHIK*

Case report

A 60-year-old male patient underwent highly selective vagotomy with dilatation of the pylorus through an anterior gastrotomy for pyloric stenosis due to chronic duodenal ulceration. The postoperative insulin test confirmed that the vagotomy was adequate. The patient remained well for 1 year, before being readmitted with recurrent vomiting, epd gastric discomfort and two episodes of malaena which lastei 2–3 days. On clinical examination there were no physical findings and the possibility of recurrent ulceration and/or restenosis was considered.

His haemoglobin was 8·0 g/dl, the white blood count, the serum electrolytes and the urea were all within normal limits. A repeat insulin gastric secretion test confirmed an adequate vagotomy. Endoscopy could not be performed because of technical problems. A barium meal examination (*Fig.* 1) showed an organo-axial volvulus of the stomach. Laparotomy confirmed the presence of the volvulus; the greater curvature of the stomach approximately 10 cm from the pylorus was the point of rotation, and this point was densely adherent to the anterior edge of the overlying liver. There was no evidence of recurrent ulceration or stenosis. The adhesions were divided and the greater curvature was separated from the colon—the so-called colonic displacement operation (Tanner, 1968). The patient was asymptomatic when seen 9 months after the operation.

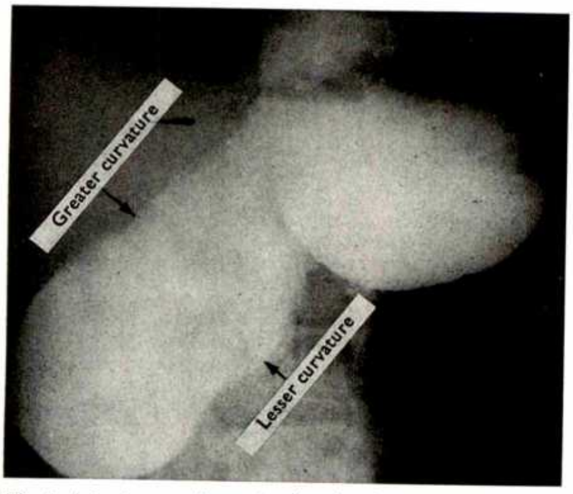

Fig. 1. A barium meal examination showing an organo-axial volvulus of the stomach.

Comment

The value of highly selective vagotomy with dilatation of the pylorus and no drainage procedure in patients with all grades of pyloric stenosis has been demonstrated (Johnson et al., 1973). However, volvulus secondary to adhesion formation has not been reported following this operation. The adhesions to the liver and a dilated hypertrophied stomach due to the previous stenosis seems to have precipitated this volvulus.

Ingrowing toenails: the results of treatment

BERNARD V. PALMER AND ANGELA JONES

SUMMARY

Completed questionnaires were received from 208 patients on whom 245 operations for ingrowing toenails had been performed at King's College Hospital. Avulsion of a strip of nail had an 83 per cent recurrence rate, total nail avulsion 70 per cent, Zadik operations 28 per cent and wedge resections 29 per cent.

It is recommended that immediate avulsion of ingrown toenails should not be a routine practice.

In many casualty departments in this country the usual treatment for acutely inflamed ingrowing toenails is immediate avulsion of the nail. The rationale for this form of treatment is that it gives immediate relief of pain. However, it is apparent that many patients return within a few months with a recurrence of their symptoms. An attempt has been made to evaluate the efficacy of various operative treatments of ingrowing toenails in a busy district teaching hospital.

Patients and methods

A questionnaire was sent to all inpatients and casualty patients who had had operations for ingrowing toenails in King's College Hospital between 1975 and 1977. They were asked for details of their operations and whether they needed or had had any subsequent treatment for the same condition.

Two hundred and sixty-nine questionnaires were sent out in June 1978. If no reply was received, a further questionnaire was sent 4 weeks later. Two hundred and eight replies were obtained, a response rate of 77 per cent.

The patients' sex and age at the time of presentation are shown in *Fig.* 1. There were 141 male patients (67 per cent) and 67 female patients (33 per cent). The mean age of presentation was 23·8 years for males and 32·4 years for females. Forty-nine per cent of all patients were below the age of 20. There was a male : female ratio amongst the patients under 30 years of age of 2·75 : 1. Above the age of 30, the ratio was virtually 1 : 1.

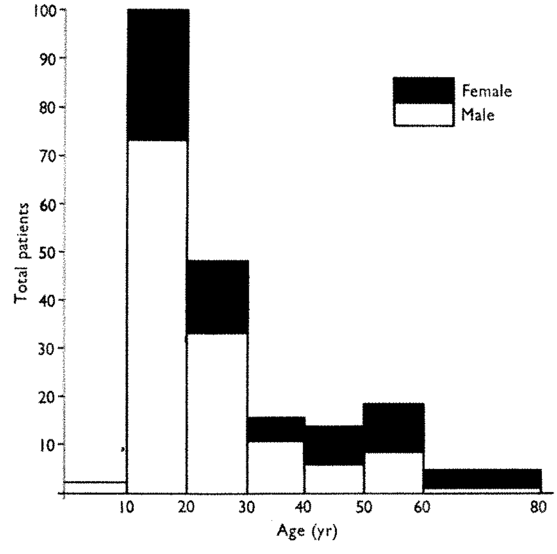

Fig. 1. Sex age distribution of the patients.

Results

Side affected

The right big toe was affected in 82 patients and the left big toe in 82 patients. Forty-four patienst (26·8 per cent of all patients) had both feet affected at the same time.

Type of operation

A total of 245 operations had been performed on 208 patients, some patients having had both feet treated at the same time.

Table I shows the type of operation performed, total avulsion of the nail being the most common treatment.

Table II shows the recurrence rate for each procedure, the most frequently used operation giving the highest recurrence rate.

There had been a variety of subsequent treatments. Nine of the patients said they had had 3 or more subsequent operations on the same toe, while 10 had had 2 subsequent operations. These procedures were usually avulsion of the nail, although 1 patient had had a total of 4 Zadik operations on the same toe!

Of the 139 patients who had required further treatment, 61·8 per cent had gone to other hospitals for this.

Table I: TYPE AND NUMBER OF OPERATIONS PERFORMED

Type of operation	No.	%
Avulsion of strip of nail	29	12
Total avulsion of nail	131	54
Wedge resection (single and double)	38	15
Total proximal nail bed ablation	47	19

Table II: RECURRENCE RATE FOLLOWING EACH OPERATION

Operation	No.	No. subsequent treatments	Recurrence rate %
Avulsion of strip of nail	29	23	83
Total avulsion of nail	131	92	70
Wedge resection (single and double)	38	11	29
Total proximal nail bed ablation	47	13	28

Discussion

There is little uniformity in the treatment of ingrowing toenails and, all too often, little understanding of the various types of treatment and their complications.

Avulsion of an ingrowing toenail is relatively simple to perform, but this survey demonstrates an unacceptably high recurrence rate of 70 per cent. Murray and Bedi (1978) recorded similar results showing a recurrence rate of 64 per cent after one avulsion and 86 per cent after a second avulsion.

---

* King's College Hospital, Denmark Hill, London.
Correspondence to: Angela Jones.

The reasons for this high recurrence are:

1. When an ingrowing toenail has been present for any length of time, the lateral nail fold becomes large and fibrosed. The new nail is frequently unable to depress this tissue as it regrows, and instead grows into it again.
2. After a nail has been avulsed, the pulp is no longer kept in place and tends to move dorsally. The new nail has to grow over this.
3. The new nail is often thickened and less pliant. As a consequence, it is less able to adapt to any soft tissue it grows against.

Avulsion of a strip of nail has a similar very high recurrence rate and for the same reasons this procedure should not be performed. The aetiological significance of poor foot hygiene, sweaty feet and the wearing of nylon socks is not known, although these factors may contribute to the high recurrence rate.

In this survey, the recurrence rate after both wedge excisions and Zadik operations was just under 30 per cent. This is still high but is similar to the rate reported by Murray and Bedi (1975). Toenail surgery is not easy, great care being necessary to ensure that the nail bed is not completely excised, but all too often the procedure is left to inexperienced doctors who are not adequately trained in the operative techniques. A wedge excision with Steristrip closure is the preferred first line operation.

In a toenail clinic at King's College Hospital it is now the policy to treat ingrowing toenails initially with antibiotics, silver nitrate applications and 1/1000 potassium permanganate soaks. Nearly three-quarters of ingrowing toenails improve within 2–3 weeks. In these cases conservative management is continued. If there has been no improvement, a curative operation is performed.

A high percentage of patients changed hospitals for subsequent treatment. Although there is no precise information, a considerable proportion of these patients had had treatment for ingrowing toenails at other hospitals before coming to King's College Hospital. This probably reflects both the lack of efficacy of the treatment and the general lack of interest in the condition shown by doctors.

Creating the healing environment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing, such as bacteria and wound debris.

Pain, oedema and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast.

Use Debrisan on all moist suppurating wounds such as pressure sores and leg ulcers.

Patients can enjoy the benefits of the healing environment of the future. Today.

Two gas-gangrene-like infections due to *Bacillus cereus*

D. J. FITZPATRICK, P. C. B. TURNBULL, C. T. KEANE AND L. F. ENGLISH*

SUMMARY

Two cases of postoperative gas-gangrene-like infection due to Bacillus cereus are reported, drawing attention to the fact that Bacillus cereus, a common environmental bacterium, can occasionally give rise to severe postoperative infection. Characteristics of the organism related to the epidemiology and pathogenesis of such infections are discussed.

RECENT interest in *Bacillus cereus* has tended to centre on its role as an agent of food poisoning. In fact, the organism has been associated with a wide variety of non-gastrointestinal infections since it was properly established under the name *B. cereus* in 1952 by Smith et al. and, for half a century before that, under various other names such as *B. subtilis, B. anthracoides, B. anthracis similis* and *B. pseudoanthracis* (Gibson and Gordon, 1974).

Apart from a paper in which aerobic spore bearers were mentioned in the context of the bacteriology of air-raid wounds (Spooner, 1941), early published reports of the involvement of these types of bacillus in wound infections have not been found, although they were associated with a wide variety of other types of infection (Turnbull, Jørgensen et al., 1979).

Recently there have been three reports of postoperative gas-gangrene-like infections due to *B. cereus* (Crum, 1976; Groschel et al., 1976; Turnbull, French et al., 1977). Two more cases are presented here, supplying further evidence that this is an organism of which surgical staff should be aware.

Case reports

Case 1: A 45-year-old compositor presented at the outpatient department in June 1977. He complained of pain in the right knee and on examination was found to have neuropathic changes in both knees, with marked valgus deformity and gross instability of the right knee. Amongst various laboratory investigations the treponemal haemagglutination (TPHA) and Khan tests were positive. The patient was diagnosed as having syphilis and penicillin therapy was instituted. The definitive treatment of the right knee was considered to be total joint replacement.

Before admission for this procedure the patient was admitted as an emergency on 1 January 1978 complaining of severe painful swelling of the right lower leg. He was apyrexic and gave no history of trauma other than energetic dancing some 24 h previously. On 2 January the calf was more tense and was decompressed. Postoperatively the patient was initially well, but when the wound was dressed on 6 January it appeared offensive. A Gram stain of the material showed Gram-positive bacilli and, as these were suspected of being a species of clostridium, penicillin therapy was started. Later when culture yielded a pure growth of *B. cereus* sensitive to gentamicin, treatment with this antibiotic was instigated.

The patient's general condition deteriorated and he became increasingly toxic and had a persistent pyrexia. An X-ray of the calf muscles revealed the presence of gas in the tissues. Total débridement of the muscles of the anterior and peroneal compartments was performed. The patient's general state remained unchanged and on 9 January a mid-thigh amputation was performed. Subsequently a wound haematoma was evacuated and the stump healed satisfactorily.

At the initial débridement operation the muscle tissue appeared avascular and bubbles of gas were noted in the deeper muscle separating the individual muscle fibres. Histological examination showed ischaemic necrosis of the muscle with suppuration following infection. Extensive venous thrombosis of the major veins of the leg antedating the onset of symptoms was noted. The appearance of the muscle was not typical of gas gangrene.

A Gram stain of the material showed Gram-positive bacilli and culture yielded *B. cereus.*

The *B. cereus* isolates were submitted to the Food Hygiene Laboratory, Colindale, for confirmation, serotyping and toxin tests.

Case 2: An 18-year-old student was admitted on 19 February 1978 following a road traffic accident. He had sustained bilateral femoral shaft fractures. His peripheral pulses were present but weak. Following resuscitation, the fractures were reduced and he was immobilized on Thomas's splints with skeletal traction.

On 20 February the circulation to the right foot gave cause for concern. A femoral angiogram was performed and occlusion of the femoral artery was noted. The thigh was explored and the fracture plated. The superficial femoral artery and vein were found to have been completely transected, at the level of the adductor tubercle. The artery was repaired utilizing a saphenous vein graft. On 21 February increased calf tension was noted and a further angiogram revealed compression of the anterior tibial vessels. Decompression of the fascial compartments of the leg was carried out.

On 24 February culture from the open leg wound produced a pure growth of *B. cereus*. The patient was grossly toxic with a persistent high temperature in the region of 39·4 °C. He was treated with cephaloridine and streptomycin. Extensive débridement of the anterior and peroneal compartment muscles was performed. At operation ischaemia of the muscle tissue was noticed with gross myonecrosis and possible gas formation deep in the tissues. Histology showed acute inflammation affecting the interstitium of the striated muscle. There was no gross muscle pathology but focal necrosis of the muscle was seen on microscopy. A wound swab taken on 27 February yielded *Pseudomonas aeruginosa* and the patient's treatment was changed to gentamicin. On 28 February a wound swab showed Gram-negative and Gram-positive bacilli and culture yielded *B. cereus* and *Proteus mirabilis*. Also one of a set of four blood cultures grew *Clostridium perfringens* on 26 February. The *B. cereus* isolates were again sent to the Food Hygiene Laboratory.

Cross-infection studies

The patients reported here were admitted to different hospitals but one member of the surgical team had operated on both cases, and initially it was considered that the cases could be related. Nose and throat swabs and hand washings were taken from the relevant personnel on 14 March 1978. *B. cereus* was isolated from the hands of the member of the surgical team common to both cases and the isolates were forwarded to the Food Hygiene Laboratory for cross-matching with the isolates from the two cases.

Bacteriology and toxicology

In *Case* 1, cultures taken on 6, 7 and 10 January all yielded *B. cereus* serotype 2. An obscure aerobic sporing bacillus, tentatively identified as *B. cirroflagellosus*, was also isolated on 7 and 10 January but the *B. cereus* was reported to have predominated. In the rabbit intestinal necrosis reaction test of Turnbull, Nottingham et al. (1977) and the skin test of Glatz et al. (1974), the *B. cereus* isolates were found to produce high levels of exotoxin (*Table I*). The two tests appear to detect the same toxin which, it has been proposed (Turnbull, 1976; Turnbull, Kramer et al., 1979), is the pyogenic and pyrogenic factor in *B. cereus* infections. The intestinal necrosis test is assessed qualitatively on a 4+ scale while, in the skin test, it has been found (Turnbull, Kramer et al., 1979) that *B. cereus* strains can be conveniently placed into five categories on the basis of the quantitatively measurable zones of reaction. The *B. cirroflagellosus* grew poorly in the growth broth used for toxin testing and could not be assessed toxigenically.

In *Case* 2 cultures taken on 24 February yielded three colonial types of *B. cereus*, a type 21 and two which could not be typed; a type 21 was again isolated on 28 February. All four isolates produced moderate levels of exotoxin (*Table I*) but insofar as they caused greater necrotic reactions in the two test systems, the NT strains were the more toxigenic.

Two apparently distinct *B. cereus* isolates were obtained some days later (14 March) from the hands of the member of the surgical team common to both cases but neither of these could be typed and both were of relatively low toxigenicity (*Table I*). Thus, they could not be related to either of the 2 cases.

Discussion

Some of the clinical features of classic gas gangrene, notably the rapid evolution of the disease, marked disorientation, delirium and prostration (Dineen, 1977), and some pathological features, e.g. spreading oedema (Robb-Smith, 1945), were not manifested in the 2 patients reported here. However, absence of these at the time of initial diagnosis was not sufficient to eliminate the possibility that these were cases of gas gangrene, and it is probable that it would always be necessary to treat this type of case as such at the outset.

In comparing the 2 cases, although many factors may have influenced the clinical features observed, it is probably relevant that the more severe infection in *Case* 1 correlated with the greater toxigenicity of the isolates from that case. In fact, in a study on the production of this toxin by *B. cereus* isolates from 21 cases of a variety of infections (Turnbull, Jørgensen et al., 1979), isolates from our *Case* 1 gave the highest readings obtained.

In *Case* 2 the roles of *P. aeruginosa*, *P. mirabilis* and *C. perfringens* cannot be definitely assessed but the facts that they were each only isolated on a single occasion and that the *C. perfringens* was not isolated from the infection site suggest that they were not of particular consequence. Transient bacteraemia with *C. perfringens* is fairly common (Ahmad and Darrell, 1976; *British Medical Journal*, 1976).

Although serotyping and toxin production results failed to establish an epidemiological relationship between the 2 cases and their 'link', this does not exclusively rule out the possibility that they were associated through this link. On the other hand, it is more likely that the infections were autogenous or were derived during dressing of the wounds. Apart from a study showing a 14 per cent carriage rate in faeces of laboratory staff (Ghosh, 1978), no published reports have been found of carriage of *B. cereus* by healthy persons. However, *Bacillus* as a group have been reported as being the most common species recoverable from the scalp (Roia and Vanderwyk, 1969), and using an adhesive tape strip test, isolation of *B. cereus* from the foreheads of staff of the laboratory of a large London Hospital was recorded as 'not common' (Taylor, 1978). Consistent isolation of *B. cereus* over a 16-week period from the hands of a member of the Food Hygiene Laboratory who worked with the organism, despite careful technique and rigorous handwashing, including a disinfectant rinse (Turnbull, unpublished results), suggests that the organism can survive well on the hands.

Spores of *Bacillus* spp. on moist or dry surfaces are highly resistant to skin disinfectants; studies reviewed by Sykes (1965) showed that sterilizing times with 2 per cent alcoholic iodine or optimal iodophore concentrations ranged from 90 min to many hours. As stressed previously (Turnbull, French et al., 1977), in preparing skin for surgery the importance of careful cleansing with detergent before application of alcoholic iodine or iodophore cannot be overemphasized.

Gas formation within the tissues was reported in one of the previous cases (Groschel et al., 1976). This is of interest in that in routine laboratory tests, *B. cereus*, in contrast to *C. perfringens*, does not produce gas to any obvious extent. However, production of gas during anaerobic reduction of nitrate is a characteristic of *B. cereus* (Smith et al., 1952) and is commensurate with the finding of gas in the tissues.

Although occasional penicillin-sensitive strains are encountered, as a group *B. cereus* organisms are β-lactamase producers. Apparently, most strains are sensitive to gentamicin (Turnbull, Jørgensen et al., 1979), which would be a reasonable choice of therapy.

Wound sepsis following gastrointestinal surgery: a comparison of topical and two-dose systemic cephradine

D. R. A. FINCH, LORRAINE TAYLOR AND P. J. MORRIS*

SUMMARY

A prospective study of the effect of the route of administration of prophylactic antibiotic on the wound infection rate following gastrointestinal surgery was performed. Patients were randomly allocated to one of three groups: group 1 received no form of antibiotic prophylaxis; group 2 received 1 g of cephradine applied topically to the wound at closure; group 3 received 1 g of cephradine intravenously at induction of anaesthesia and a further intravenous dose of 500 mg 4 h later. Wound infections occurred in 12 of 83 patients in the control group (14·5 per cent), in 6 of the 83 patients in the group who received topical antibiotic (7·2 per cent) and in 3 of the 82 patients who received systemic antibiotics (3·6 per cent). Only the group who received systemic antibiotic showed a statistically significant reduction in the incidence of wound infections compared with the control group ($P = 0.03$).

WOUND infection rates of 9–22 per cent are commonly seen following gastrointestinal surgery, even if patients in whom pus is present at operation are excluded (Cruse and Foord, 1973). Although infection rates can only be reduced to acceptable levels by employing meticulous standards of surgical technique, the additional use of prophylactic antibiotics administered either topically into the wound or systemically during surgery has become increasingly popular in recent years (Keighley, 1977). However the value of such prophylactic regimens is still questioned (Spievack, 1978).

The present study was planned to examine the effect of the broad spectrum antibiotic cephradine on the incidence of postoperative wound infection after gastrointestinal surgery, and to compare the effect of topical administration of the antibiotic with systemic administration of the same antibiotic.

Patients and methods

Patients admitted to the Nuffield Department of Surgery for gastrointestinal surgery (both elective and emergency) during the 11-month period from August 1977 to July 1978 were entered into the trial. Immediately before surgery, patients were allocated to one of the three arms of the trial by opening sealed envelopes containing previously randomized cards: group 1, control group—no antibiotic treatment; group 2, topical antibiotic—1 g cephradine administered topically into the wound at the time of closure; group 3, systemic antibiotic—1 g cephradine administered intravenously at the time of induction of anaesthesia and 500 mg administered intravenously 4 h later.

For the duration of the trial all wounds were closed with continuous nylon sutures with the exception of muscle-splitting incisions which were closed with chromic catgut. Wounds were not drained unless the subcutaneous fat exceeded 2·5 cm and all peritoneal drains were brought out through separate incisions. Bowel preparation before colonic surgery was by mechanical means only.

Wounds were inspected daily from the fourth postoperative day by a research nurse who was unaware of the group into which the patient had been allocated. Wound sepsis was defined as the presence of pus in a wound which spontaneously discharged or had to be released by removing sutures and opening the incision (National Research Council, 1964). Swabs were taken from infected wounds by the research nurse and delivered immediately in Stuart's medium to the laboratory for both aerobic culture on blood agar and MacConkey's medium and anaerobic culture on blood agar with 100 μg/ml of neomycin sulphate. Those patients discharged from hospital with their sutures still in place were supplied with a form to be completed by the doctor or nurse at the time of suture removal. Evidence of wound infection was also sought at the routine follow-up clinic 4–6 weeks later.

Subsequently excluded from the trial were all patients who were found at operation to have a bacterial peritonitis secondary to perforation of the small bowel, appendix or colon. Such patients were classified as having 'contaminated' rather than 'potentially contaminated' wounds (Pollock, 1976) and further therapeutic measures were left to the discretion of the surgeon. Also excluded from the trial were all patients who received additional antibiotics within 24 h of surgery, for whatever cause.

Results were analysed for statistical significance by the use of χ^2 test with Yates's correction.

Results

Exclusions (Table I)

Two hundred and eighty patients were originally entered into the trial. At operation 26 patients were found to have a bacterial peritonitis and were subsequently excluded (23 patients with perforation of the appendix, 2 patients with perforation of the small bowel and 1 patient with a colonic perforation). Six of the remaining patients received additional antibiotics either at operation or within 24 h and were also excluded. Three of these patients had salpingitis and normal appendices were removed, 1 patient with carcinoma of the colon had a urinary tract infection and 1 patient underwent abdominoperineal excision of the rectum and total cystectomy with gross faecal soiling of the abdominal cavity. The final patient underwent a prolonged operation on the biliary tract. In the last two patients the surgeon involved felt that a full course of antibiotics was indicated.

Distribution of uncontrolled variables

There was an even distribution between the three groups with respect to age of the patients, experience of the surgeon and acute or elective nature of the operation. Wound drains were employed in a total of 8 patients (4 patients in the control group, 1 in the group that received topical antibiotic and 3 in the group that received systemic antibiotic).

Wound infections (Table II)

Twelve wound infections (14·5 per cent) occurred in the control group of 83 patients who received no antibiotic at the time of operation. Six wound infections were recorded in the group of 83 patients who received topical antibiotic (7·2 per cent) but this result did not differ significantly from that recorded in the control group ($\chi^2 = 1·56$, $P > 0·05$). Three wound infections occurred in the group of 82 patients who received systemic antibiotic (3·6 per cent) and the difference between this figure and that recorded in the control group was significant ($\chi^2 = 4·59$, $P = 0·03$). In this group the three infections followed appendicectomy in two patients (one normal and one gangrenous) and a left hemicolectomy for carcinoma in a third patient. However, the difference between the infection rates in the two groups receiving antibiotic prophylaxis was not significant ($\chi^2 = 0·04$, $P > 0·05$).

---

* Nuffield Department of Surgery, University of Oxford, Radcliffe Infirmary, Oxford.

Bacteriology (*Table III*)

Table III summarizes the organisms isolated from the 21 infected wounds in this series. *Staphylococcus aureus* was isolated from 7 wounds in the control group but from none of the wounds in the two treated groups. *Clostridium welchii* was isolated from 2 of the patients in the control group and from 1 patient who received topical antibiotic. One of the patients in the control group developed clinical gas gangrene of the wound and subsequently died. *Bacteroides fragilis* was isolated from a total of 6 wounds; 3 in the control group, 2 in the topical antibiotic group and 1 in the systemic antibiotic group.

Other septic complications (*Table IV*)

Fifteen patients in the control group developed other significant infective complications after surgery. Ten patients developed chest infections and 5 patients developed infections of the urinary tract. In the group receiving topical antibiotic, 13 infective complications were recorded, including 2 patients who each developed a pelvic abscess. In the group who received systemic cephradine only 6 such complications occurred (this was not significantly different from that recorded in the control group, $\chi^2 = 3·7$, $0·05 < P < 0·1$).

Discussion

These results show that a significant reduction in the wound infection rate following gastrointestinal surgery can be achieved by the systemic administration of two doses of the broad spectrum antibiotic cephradine at the time of surgery. This two-dose regimen is designed to give a maximum tissue concentration of antibiotic at the time of contamination and is based on the classic experimental studies of Burke (1961). He demonstrated in the guinea-pig that a single intravenous dose of antibiotic given at, or just before, intradermal inoculation of bacteria was the most effective method of preventing the development of infected lesions and that the antibiotic was completely ineffective if given more than 3 h after inoculation. This regimen does not favour the emergence of antibiotic-resistant strains of bacteria provided a bactericidal drug is used. Cephradine was selected for use in this trial because of its broad spectrum of activity which includes *Staphylococcus aureus* and most of the common bowel pathogens. It has been shown to have a high resistance to β-lactamases (Selwyn, 1976) and has activity against some anaerobic bacteria including some *Bacteroides* species (Shadomy et al., 1977).

Urinary tract infection	5	5	2
Pelvic abscess	0	2	0
Total	15	13	6

Control *v.* systemic, $\chi^2 = 3·7$, $0·05 < P < 0·1$.

These results further suggest that the use of systemic antibiotic prophylaxis is more effective than the topical application of the antibiotic at the end of the operation. In view of the experiments of Burke (1961) this is not surprising, as the antibiotic is being added to the wound after contamination has occurred. Although topical cephradine failed to reduce significantly the wound infection rate, a larger trial would have been necessary to have demonstrated a statistically significant difference between this group and the group that received systemic antibiotic.

A further disadvantage of topical antibiotics has been noted by Keighley (1977), namely that they are unlikely to affect the incidence of infective complications outside the wound. Our data would support this suggestion. In this series the incidence of such complications in the group receiving topical antibiotic was very similar to that seen in the control group. In the group receiving systemic antibiotic, the incidence of such complications was reduced from 15 to 6 per cent, but these figures just failed to reach the level of significance.

The infection rate of 14·5 per cent recorded in the untreated control group in this study is relevant to the discussion. Spievak (1978), in his editorial 'The prophylactic antibiotic puzzle', has pointed out that a significant reduction in the wound infection rate in most published series has only been recorded when the infection rate in the control group is in the range of 20–60 per cent, a figure that he considers unacceptably high. Inspection of the infection rates quoted by Keighley (1977) in his recent review lends support to this argument. All 18 of the published series cited in which the infection rate in the control group exceeded that reported in this series showed a significant reduction in infection rates in the antibiotic-treated groups. However, in only 3 of the 8 series cited in which the control infection rate was lower than that reported here was this infection rate lowered by prophylactic antibiotics. The infection of 14·5 per cent reported here, whilst failing to meet the figure of 5 per cent demanded by Spievak in clean cases, is entirely acceptable in our opinion as this study included only patients with 'potentially contaminated' wounds. Furthermore, the majority of operations were performed as emergency procedures by surgeons below the grade of consultant.

Burdon et al. (1978) have reported recently the failure of systemic cephalothin given at surgery to reduce significantly the wound infection rate following colonic surgery. This may have been due to low resistance of cephalothin to β-lactamase compared with cephadine, and to cephalothin's greater affinity for protein binding resulting in lower tissue levels of free antibiotic (Selwyn, 1976). In the present series the most noticeable reduction in wound sepsis appeared to occur amongst the patients who underwent colorectal surgery. Only 1 wound infection occurred in the 14 patients who received systemic cephradine compared with 4 infections in the 14 who received topical antibiotic and 3 infections in the 8 patients in the control group. However, the numbers in these groups are too small to reach statistical significance.

In view of the recent interest shown in evaluating the importance of anaerobic organisms in the pathogenesis of wound sepsis, particular attention was paid in this trial to the collection of material for anaerobic culture (Kelly and Warren, 1978). *Bacteroides fragilis* was isolated from 6 of the 21 infected wounds in this series (29 per cent), a similar figure to that recently reported by Pollock et al. (1978). However, *Bacteroides fragilis* alone was cultured from only one of the infected wounds in the group that received systemic antibiotic and from two of the wounds in the group that received topical prophylaxis. It is thus doubtful whether the additional prophylactic administration of an agent active only against anaerobic organisms would confer any significant advantage in patients undergoing potentially contaminated gastrointestinal surgery over the use of a single broad spectrum antibiotic such as cephradine, whose range of clinical activity includes some of the anaerobic pathogenic bacteria (Shadomy et al., 1977).

Conclusions

A simple two-dose course of systemic cephradine given at the time of surgery can reduce the wound infection rate following gastrointestinal surgery to a level of 3·5 per cent even when the infection rate in patients not receiving antibiotic prophylaxis is as low as 14·5 per cent. This regimen appears more effective than the topical application of antibiotic into the wound which did not significantly reduce the postoperative infection rate. It is unlikely that any significant further improvement would be obtained by the addition of an agent specifically active against anaerobic organisms.

Leucocyte ascorbate levels and postoperative deep venous thrombosis

T. V. TAYLOR, A. T. RAFTERY, J. B. ELDER, CHRISTINE LOVEDAY, I. W. DYMOCK, A. C. C. GIBBS, JULIE JEACOCK, S. B. LUCAS AND M. A. PELL*

SUMMARY

Forty-four general surgical patients were included in a prospective, randomized double-blind controlled trial of ascorbic acid (500 mg b.d.) or placebo for 7 days before operation. This was to test the hypothesis that vitamin C may reduce the instance of deep venous thrombosis postoperatively. Venous blood samples were taken before entering the trial, just immediately before surgery, on the day of operation and on three further occasions at 3-day intervals postoperatively for leucocyte ascorbic acid concentration (LAC). Venous thrombosis was diagnosed using the ^{125}*I-fibrinogen test and the leg scans interpreted by Roberts' criteria. There was no significant difference in the incidence of DVT between the treatment and placebo groups. In those with DVT* (n = *23) the mean LAC on the day of operation was not significantly different from that in those without DVT. However, on the sixth and ninth postoperative days LAC levels were significantly lower in the DVT group. These results suggest that the administration of ascorbic acid preoperatively does not reduce the incidence of DVT, but a striking decrease in the LAC levels in the DVT patients is in keeping with the hypothesis that the initial event in the pathogenesis of DVT is adherence of leucocytes to the venous endothelium.*

It is claimed that in the United Kingdom approximately 21 000 patients die each year from pulmonary embolism (DHSS, 1970) and, while the case for prophylaxis for deep venous thrombosis has recently been reviewed (Kakkar, 1977), considerable controversy exists as to the best methods. Currently available methods are aimed at preventing deep venous thrombosis by elimination of stasis in the deep veins and by counteracting changes in blood coagulability. Low dose subcutaneous heparin is widely used (Kakkar et al., 1975) but excessive blood loss during and after operation, thrice daily injections and, perhaps less significantly but important none the less, the economic implications of this therapy have all restricted its use. Spittle (1973), believing that vitamin C is necessary for the provision and maintenance of a healthy ground substance of blood vessel walls, suggested a role for vitamin C therapy as a prophylactic against postoperative deep venous thrombosis and provided data to support her view. Andrews and Wilson (1973), using a much smaller dose of vitamin C, could not confirm Spittle's report. Should vitamin C be effective then its well-known freedom from side effects, ease of administration and low cost would make it an attractive alternative in clinical practice. The question of the usefulness of vitamin C in preventing deep venous thrombosis remained open and clearly required further study.

Patients and methods

A prospective randomized double-blind controlled trial has been carried out in 43 general surgical patients allocated to either vitamin C 500 mg twice daily or placebo tablets twice daily. Treatment commenced 7 days before and stopped on the day immediately before surgery. Samples of venous blood for leucocyte ascorbate estimations by the method of Denson and Bowers (1961) were taken before treatment, again on the day of operation and on three further occasions postoperatively at 3-day intervals. Venous thrombosis was diagnosed by the ^{125}I-fibrinogen test using the criteria of Roberts (1975).

Patients were scanned preoperatively and then daily for at least 7 days. Special importance was attached to analysis of the results by the method of Roberts in an attempt to overcome inaccuracies produced by variations in background radioactivity, possible misplacement over the precordium and by variations in blood volume in the lower limb produced by vasoconstriction or dilatation. Leg counts were referred to the 'preoperative baseline' rather than to counts made immediately after operation (Kakkar et al., 1970). All data, including recordings of weight, age, initial haemoglobin, haematocrit, presence or absence of malignancy, premedication drugs, details of intravenous fluids, smoking history, day of postoperative mobilization, thrombus score (number of elevated points on limb × the number of days the point was elevated) and the leucocyte ascorbate concentration (LAC), were transferred to punch cards before processing on a CDC 7600 computer. Patients excluded were those over the age of 70 years and, for technical reasons, those undergoing varicose vein or reconstructive peripheral arterial surgery. Twenty patients received ascorbic acid and 23 placebo. The treatment and placebo groups were not significantly different from each other initially (*Table I*). All probabilities shown are two-tailed, except where otherwise stated.

Results

The treatment and placebo groups had a significantly different mean LAC on the day of operation (P = 0·001) (*Table II*) and these differences remained up to the sixth postoperative day. By the ninth day there was no significant difference in leucocyte ascorbic levels between the two groups. In the treatment group 9 of 20 patients, and in the placebo group 13 of 23, developed deep venous thrombosis as detected by the ^{125}I-fibrinogen test. This difference is not statistically significant (corrected χ^2 = 0·2, d.f. = 1, P = 0·65, *Table III*). These findings are in conflict with those of Spittle (1973) but in agreement with those of Andrews and Wilson (1973). A thrombus score was formulated comprising the sum of the number of days on which the radioactivity at each point was elevated and again there were no significant differences between the two groups using the Mann–Whitney U test on the thrombus score (*Table IV*).

There was a marked postoperative reduction by day 3 in the leucocyte ascorbate concentration; the reduction was similar in magnitude in both the ascorbic acid and placebo groups, each showing an

almost parallel decrease in the levels (*Fig.* 1). In the placebo group the LAC rose gradually between the third and sixth postoperative days and then sharply between the sixth and ninth, bringing the level up almost to that in the patients treated with ascorbic acid. Considering our patients as thrombus and non-thrombus groups irrespective of whether they received ascorbic acid or not, analysis has revealed an interesting trend (*Fig.* 2). Leucocyte ascorbate curves show separation occurring from the day of operation. Between day 3 and day 6 the curves move in opposite directions, a marked increase occurring in the non-thrombus group but clearly a decrease in those who develop venous thrombosis. There was no difference between the LAC levels in the thrombus and non-thrombus groups at the initial outpatient assessment and on the day of operation. The decrease in LAC levels at the third postoperative day became statistically significant by days 6 and 9 postoperatively (*Fig.* 2). This suggests that the presence of thrombus may actively reduce the LAC.

The thrombus score was found to be significantly correlated with smoking, preoperative haemoglobin concentration, the LAC level on the sixth postoperative day and the patient's weight (*Table V*). There was a negative correlation with smoking habits ($P = 0{\cdot}007$). The more cigarettes smoked, the smaller was the thrombus score for the patient who developed a positive ^{125}I-fibrinogen scan. There was no significant correlation of thrombus score with age, sex, intravenous fluid regimen and, surprisingly, with the day of mobilization after operation.

Discussion

It is of interest that leucocyte ascorbate levels became significantly lower postoperatively in patients developing venous thrombosis. LAC may possibly act as a monitor of the thrombotic process. This hypothesis accords with the observations of Cooke and his colleagues (1977), who found that thigh vein thrombi were invariably attached to at least one point of the venous wall even as early as the first postoperative day. It is known that endothelial damage, whether surgically induced or not, is soon followed by leucocyte adhesion and invasion of the vein wall (Stewart et al., 1978). The mechanism of reduction in LAC in our study may be related to the size and degree of propagation of the thombus.

It could also be argued that low LAC levels in our thrombosis group indicate a failure of the prescribed dose of the vitamin C to maintain LAC levels and that if larger doses had been given then the postoperative fall in LAC may not have occurred and possibly the outcome as far as thrombosis is concerned would have been different. We have not, however, examined different doses in the present paper and there is scope for further work in this regard.

Smoking, haemoglobin concentration, LAC at 6 days postoperatively and weight are all significantly correlated with the thrombus score (*Table* V). Current theories of the aetiology of deep venous thrombosis have been well summarized recently (Morris and Mitchell, 1977) but curiously this and other authoritative reviews (Kakkar, 1977) have failed to comment on the role of cigarette smoking. Our findings surprisingly indicated that venous thrombosis was less likely and, when it occurred, less severe in those who smoked ($P = 0{\cdot}007$). Similarly, Handle and Teather (1969) noted in patients after myocardial infarction that non-smokers had a significantly higher incidence of deep vein thrombosis than cigarette smokers, a result confirmed independently by Marks and Emerson (1974). In a further study Emerson and Marks (1977) found, again after myocardial infarction, that leg vein thrombosis developed in 12 (50 per cent) of 24 patients who did not smoke cigarettes and in only 2 (13 per cent) of 17 patients who were cigarette smokers. An independent study also using the ^{125}I-fibrinogen test in patients after major surgery compared the incidence of DVT in cigarette smokers and pipe smokers with that in non-smokers, emphasizing that it appeared to be cigarette smoking rather than pipe smoking which 'protected' (Pollock, 1978). It appears that cigarette smoking seems to be almost as effective in preventing leg vein thrombosis as low dose heparin (Emerson and Marks, 1977).

Table V: CORRELATION OF VARIABLE WITH THROMBUS SCORE

Variable	Spearman's rank correlation coefficient	P
Smoking	−0·449	0·007
Haemoglobin	0·3116	0·047
LAC 6 days	−0·303	0·05
Weight	0·357	0·03

Interpretation of these data is difficult and further study appears justified, perhaps using the approach of Clayton et al. (1976), employing relatively easily obtainable data such as smoking habits, age, weight, presence of varicose veins and euglobulin clot lysis time in a logistic discrimination analysis aimed at acceptable preoperative prediction of postoperative venous thrombosis.

Leg haemodynamics during reconstructive vascular surgery

T. SONNENFELD, R. CRONESTRAND AND J. NOWAK*

SUMMARY

The aim of this study was to find the best haemodynamic variables for a correct assessment of the function of a femoropopliteal bypass graft. The results are based on intraoperative measurements performed on 11 patients undergoing surgical reconstruction of the femoral artery with a femoropopliteal reversed saphenous vein bypass graft.

Both blood transfusion and local intra-arterial injection of 40 mg of papaverine resulted in a significant increase in common femoral arterial and graft blood flows as well as in femoropopliteal pressure difference. At the same time there was a significant decrease in total leg and lower leg resistance, whereas the resistance over the graft was not significantly altered by changes in blood volume or by pharmacological vasodilatation.

It was shown that, for a complete assessment of the bypass function, both the resistance in the graft and in the lower leg must be evaluated. This can be effected by simultaneously measuring both the blood pressure and the blood flow. It was also shown that the femoropopliteal pressure difference per se does not indicate the true capacity of the graft. It is concluded that, during reconstructive vascular surgery, leg haemodynamic variables are influenced by variations in blood volume and vasomotor tone. This is of importance for the correct interpretation of a single haemodynamic variable and for the correct quantitative evaluation of the results of vascular surgery.

THE aim of vascular reconstructive surgery is to restore an adequate blood flow, and the immediate effect of a successful operation is an increased blood flow through the reconstructed vessel and a reduced pressure gradient across it. For the intraoperative evaluation of the results of the reconstructive procedure, most vascular surgeons rely upon flow measurements only, which is sufficient in most cases. Misleading conclusions can be drawn, however, if these measurements are based on either pressure recordings or flow measurements alone, as these two variables depend on each other. Furthermore, there are great variations during surgery in the intravascular volume and, consequently, in peripheral vascular resistance, which both influence blood flow.

The aim of this investigation was to study how, during reconstructive vascular surgery, the peripheral vascular resistance and, consequently, the blood flow in the legs are influenced by changes in intravascular volume and by pharmacological vasodilatation with papaverine, a drug frequently used to estimate flow capacity in reconstructed segments (Cappelen and Hall 1964; Dedichen, 1973).

Patients and methods

Patients

Eleven male patients with a mean age of 58 years (range 47–71) were studied during reconstruction with a femoropopliteal reversed saphenous vein bypass graft. They were all operated on because of symptomatic atherosclerotic occlusion of the superficial femoral artery. The indications for surgery were intermittent claudication in 10 patients and rest pain in 1 patient. None of the patients suffered from gangrene. Two had diabetes mellitus. All the patients underwent preoperative arteriography to determine the extent of arterial occlusion and the degree of atherosclerotic involvement of the popliteal artery and its three branches. Outflow in the lower leg arteries was graded according to Hall (1964) as good (grade A) when all the three lower leg arteries were open with fairly good calibres and even contours (10 patients) and as bad (grade B) in the remaining 1 patient.

Preoperative examinations included chest X-ray, an exercise test with ECG recordings and spirometry. Five patients showed moderate ECG changes during exercise, indicating ischaemic heart disease, and 1 patient showed signs of obstructive pulmonary disease.

The patients were fully informed of the objective and procedure of the study before their free consent to participate was obtained. The protocol was reviewed and approved by the ethical committee of the Karolinska Institute at Huddinge Hospital.

Methods

The patients were premedicated with 5–7·5 mg of droperidol (Dridol), 5–10 mg of diazepam (Valium) and 0·5 mg of atropine intramuscularly. Anaesthesia was induced by 5–10 mg of droperidol, 0·3–0·5 mg of fentanyl (Leptanal) and 5–8 mg of pancuronium bromide (Pavulon). The patients were ventilated mechanically with nitrous-oxide–oxygen (2 : 1) through an Engström ventilator (model 300) with minute volumes set according to the nomogram of Engström and Herzog (1959). An even depth of anaesthesia was maintained by additional doses of fentanyl (0·1–0·3 mg/h) and pancuronium bromide (0·1–1·8 mg/h).

The reconstruction with a femoropopliteal saphenous vein bypass graft was performed without blood transfusion. After completion of the reconstructive procedure, measurements of blood flows and recordings of blood pressures were performed before and during vasodilatation, induced by injecting 40 mg of papaverine into the common femoral artery. Flow measurement and pressure recordings were performed simultaneously and were followed by transfusion of 900 ml of warmed blood (37 °C). After 5–10 min, when a steady state was reached, the measurements were repeated before and during vasodilatation.

Flow measurements: Blood flows in the vein bypass graft and common femoral artery were measured with a square-wave electromagnetic flowmeter (Nycotron, model 376, Norway) (Cappelen and Hall, 1967). The calibration factors for the probes given by the manufacturer were used. Zero flow references were obtained by mechanical occlusion of the vessels (Schenk and Dedichen, 1967).

Pressure measurements: In 8 patients a Teflon catheter (outer diameter 1·2 mm) was inserted percutaneously into the brachial artery and advanced to the subclavian artery. In all 11 patients 2 similar Teflon catheters were inserted into the bypass vein through tributaries and advanced to the common femoral artery proximal to the upper anastomosis and to the popliteal artery distal to the lower anastomosis, respectively.

Pressure recordings were performed with pressure transducers of the variable capacitance type (EMT 34, Siemens-Elema AB, Sweden) with the mean pressures obtained by electrical damping. The vertical midpoint between the sternal bone at the 4th intercostal space and the back was used as a zero reference level.

* Departments of Surgery and Clinical Physiology, Karolinska Institute, Huddinge Hospital, S-141 86 Huddinge, Sweden.

Calculation of peripheral resistance: Peripheral resistance values for the whole leg and the lower leg were calculated from the pressure and flow values registered in the common femoral and popliteal arteries respectively. The resistance over the bypass graft was calculated by dividing the difference between the pressure in the common femoral and popliteal arteries by bypass flow. The resistance values are given in peripheral resistance units (PRU).

The ECG was monitored continuously and recorded on a Mingograph 61 (Siemens-Elema AB) as well as the signals from the flowmeter and the pressure transducers.

The total blood loss before transfusion was calculated from volume measurements in the suction apparatus and from drapes and swabs: the average was 550 ml (range 350-700). Thus, the patients were deliberately marginally overtransfused with blood (350 ml on average) to offset early postoperative haemorrhage (Hoye et al., 1961).

Statistics: Data in the text and figures are given as mean ± standard deviation. To test the significance of differences, Student's paired *t* test was used.

Results

The results are summarized in *Table I* and *Figs.* 1–3.

Effect of blood transfusion

Before blood transfusion the basal blood flow in the common femoral artery was 160 ± 58 ml/min. Following transfusion, it increased by, on average, 171 per

* Four Dacron bypasses and endarterectomies.

cent, to 433 ± 159 ml/min ($P<0{\cdot}001$). The corresponding flow values in the bypass vein were 81 ± 46 and 215 ± 67 ml/min respectively, implying an increase of 165 per cent ($P<0{\cdot}001$) after transfusion. Simultaneous changes in blood pressures were much less pronounced and not significant ($P>0{\cdot}05$). Thus, after transfusion, the mean pressures in the subclavian and common femoral arteries increased from 13·2 ± 2·4 kPa and 12·9 ± 2·9 kPa respectively to 14·0 ± 3·1 kPa and 14·1 ± 2·8 kPa respectively. The mean pressure in the popliteal artery showed a slight, not significant decrease from 11·1 ± 3·2 kPa before blood transfusion to 10·7 ± 2·3 kPa after transfusion. However, as a result of these slight pressure changes in the common femoral and popliteal arteries, the femoropopliteal pressure difference increased significantly following blood transfusion from 1·9 ± 1·6 kPa to 3·4 ± 1·9 kPa ($P<0{\cdot}01$). Since the pressures in the common femoral and popliteal arteries were not significantly affected by transfusion, the increased femoral and bypass blood flow rates after transfusion must have been due to decreased vascular resistance in the leg. In fact, the mean vascular resistance for the whole leg and the lower leg decreased significantly ($P<0{\cdot}001$) after transfusion by 61 ± 14 per cent and by 62 ± 15 per cent respectively. The resistance over the graft was not affected by blood transfusion. After transfusion it was 0·019 ± 0·015 PRU.

Effect of pharmacological vasodilatation

Before blood transfusion vasodilatation caused an increase in common femoral arterial and bypass blood flows by, on average, 364 per cent to 719 ± 239 ml/min ($P<0{\cdot}001$) and by 274 per cent to 278 ± 109 ml/min ($P<0{\cdot}001$) respectively. Simultaneously, the mean femoral and popliteal blood pressures decreased significantly by 18 ± 7 per cent ($P<0{\cdot}001$) and 28 ± 10 per cent ($P<0{\cdot}001$) respectively. Consequently, parallel with the increase in common femoral arterial and bypass blood flow rates following vasodilatation was a decrease in vascular resistance in the whole leg and in the lower leg. This decrease in resistance following vasodilatation amounted to 81 ± 7 per cent ($P<0{\cdot}001$) in the whole leg, and 78 ± 8 per cent ($P<0{\cdot}001$) in the lower leg.

After blood transfusion there was still a significant increase in blood flow during vasodilatation. Thus, in the common femoral artery, the blood flow increased by, on average, 135 per cent to 1017 ± 429 ml/min ($P<0{\cdot}001$). The corresponding values for the bypass graft were 72 per cent and 373 ± 136 ml/min ($P<0{\cdot}001$) respectively. Also, after transfusion vasodilatation caused a significant decrease in the mean common femoral and popliteal arterial blood pressures by, on average, 14 per cent to 12·3 ± 2·7 kPa ($P<0{\cdot}001$) and 28 per cent to 7·7 ± 1·7 kPa ($P<0{\cdot}001$) respectively. Thus, a decreased vascular resistance in the whole leg and in the lower leg accompanied increased common femoral and bypass blood flows. However, these changes in vascular resistances following vasodilatation, though still significant, were less pronounced after blood transfusion as compared to values before transfusion. Thus, after transfusion, vasodilatation caused a decrease in whole leg resistance by 56 ± 9 per cent ($P<0{\cdot}001$) and in lower leg resistance by 57 ± 7 per cent ($P<0{\cdot}001$).

The pressure gradient over the bypass graft increased after vasodilatation. Before transfusion, however, the increase from 1·9 ± 1·6 kPa to 2·7 ± 2·4 kPa was not significant, while after transfusion the increase from 3·4 ± 1·9 kPa to 4·6 ± 2·8 kPa was statistically significant ($P<0{\cdot}05$). However, with these increases in pressure difference there were parallel increases in flow rates in the bypass graft. Resistance of the graft did not change significantly during vasodilatation neither before nor after transfusion. The graft resistance was low at each measurement: furthermore, following vasodilatation, it was less than the lower leg resistance, both before and after transfusion.

Blood pressure in the subclavian artery decreased significantly during vasodilatation by 8 ± 4 per cent ($P<0{\cdot}01$) before transfusion and by 8 ± 5 per cent ($P<0{\cdot}01$) after transfusion.

Graft patency

Based on history, the presence of a palpable pulse either in the graft or distal to it and oscillometric measurements, all patients had patent grafts and showed a marked improvement at follow-up 13–24 months (mean 18 months) after operation.

Discussion

In the present study it was shown that both an increase of the intravascular volume and the intra-arterial injection of a vasodilatory drug have a marked effect on vascular resistance in the leg.

Augmenting the intravascular volume by whole blood transfusion significantly decreased the peripheral resistance. As leg blood pressure was not significantly altered by transfusion, the decrease in vascular resistance was accompanied by a marked increase in blood flow.

The variation in leg resistance with different intravascular blood volumes explains the wide range of bypass flow values reported (*Table I*). Intravascular volume also affects the response to vasodilatation. Thus, the percentage flow increase in the graft after dilatation before blood transfusion was much higher than after transfusion. Therefore, the marked flow increase (+300 per cent) reported by Barner et al. (1968) may have been due to hypovolaemia and does not necessarily reflect the true physiological reactiveness of the distal vascular bed in a normovolaemic situation.

The presence of a residual femoropopliteal pressure difference after vein grafting was noted in all patients, although the reconstructions were successful. When the circulating blood volume was increased, the femoropopliteal pressure difference showed a further significant increase. The resistance of the graft itself, however, was unchanged following blood transfusion, implying that the increase in pressure difference was accompanied by an adequate flow increase in the bypass graft. The resistance of the bypass vein in all patients was less than that of the lower leg, indicating that the graft was functioning adequately and that it did not obstruct the blood flow.

From the present findings it is apparent that the femoropopliteal pressure difference does not *per se* indicate the capacity of the graft. The pressure difference should always be evaluated together with the blood flow through the graft. Thus, a significant increase in flow rate together with a moderate pressure gradient increase following blood transfusion indicates a good reconstruction, whereas an increase in pressure gradient without an accompanying flow increase indicates an ineffective bypass graft or a technical fault, such as too narrow an anastomosis. The resistance of the graft itself must also be related to the lower leg resistance. Thus, if the resistance of the graft is higher than that of the lower leg, the implication is that the graft obstructs the blood flow.

Compared with the results of other studies, the femoropopliteal pressure difference obtained in the present study after adequate blood substitution was high. Our opinion that the low femoropopliteal pressure difference previously reported was caused by hypovolaemia is supported by the fact that bypass flow values in the same patients were also low (*Table I*). This supports the importance of blood volume for the correct interpretation of a regional heamodynamic variable.

The further increase in femoropopliteal pressure gradient after vasodilatation reflects the relatively limited and fixed lumen capacity of the graft. We therefore do not support the contention of Bliss (1973) that an increase in pressure gradient after papaverine injection should indicate a technical fault. On the other hand, a major increase in pressure gradient might indicate a technical error or a graft with too small a calibre. However, in the present study, in 7 of the 11 patients the femoropopliteal pressure difference exceeded 3·0 kPa after adequate blood transfusion without the presence of a technical fault.

The peripheral resistance was also significantly altered by blood transfusion. The lower leg resistance (run-off resistance) before blood transfusion was within the same range as in the patients reported by Mundt et al. (1969) and by Bliss (1973), whereas resistance values in the present study after transfusion were significantly lower. This supports the idea that the patients reported by the quoted authors were hypovolaemic.

The injection of papaverine also markedly reduced the peripheral resistance. However, the decrease in resistance was significantly more pronounced before than after blood transfusion. Thus, the response to vasodilatation gives valuable information about the state of volume substitution. There was a significant decrease in subclavian, femoral and popliteal arterial pressures after vasodilatation, indicating a systemic effect exerted by papaverine after regional arterial injection. This should be taken into account when injecting this agent in a patient who is hypovolaemic to a significant degree.

The effect of papaverine on the peripheral resistance is important for a correct evaluation of the maximal flow capacity of the bypass graft. Thus, the flow rate obtained in the graft following papaverine injection after adequate volume substitution should be comparable to that following physiological stimulation, i.e. leg exercise, because, in the present investigation, the resistance in the leg following vasodilatation showed no marked difference before and after blood transfusion.

Solitary toxic adenoma of the thyroid gland

C. J. BRANSOM, C. H. TALBOT, L. HENRY AND J. ELEMENOGLOU*

SUMMARY

The incidence of solitary toxic adenoma of the thyroid in a general surgical unit with an interest in thyroid disease has been reviewed over a 15-year period. Six hundred and thirty thyrotoxic cases were treated surgically, 35 (5·6 per cent) having a solitary toxic adenoma. Thyroid enlargement or toxicity had been present for more than 5 years in 7 patients (20·0 per cent). Cardiovascular complications were present in 6 cases (17·1 per cent).

Thyroid lobectomy resulted in 30 (85·7 per cent) euthyroid and 5 (14·3 per cent) hypothyroid patients. One toxic adenoma contained a focus of carcinoma. The clinical features, diagnosis and management of solitary toxic adenoma, and the management of symptomatic nodules which are 'hot' but not biochemically toxic, are discussed.

THE pathological diagnoses of patients undergoing surgery for thyroid disorders in one unit of the Sheffield Royal Infirmary over the 15 years 1963–77 were reviewed retrospectively. The radioisotope thyroid scans performed in the hospital between these years were also surveyed. The clinical details, biochemical and scan data, operative findings and histological material of patients with a possible solitary toxic adenoma were then examined.

Patients and methods

Between 1963 and 1977 a total of 1228 patients in the unit underwent thyroid operations. Six hundred and thirty patients were thyrotoxic (51·3 per cent). A total of 165 solitary adenomas was removed, of which 35 were toxic, representing 21·2 per cent of the adenomas and 5·6 per cent of the total toxic cases managed surgically (*Table I*). Seven cases of solitary adenoma had clinical features suggesting thyrotoxicosis, but protein-bound-iodine and radio-iodine uptake levels were normal. These patients have been classified as having solitary non-toxic adenomas.

Table I: OPERATIONS FOR TOXIC THYROID DISEASE 1963–77

Diagnosis	No.	%
Graves's disease (toxic hyperplasia)	367	58·2
Toxic multinodular goitre	228	36·2
Solitary toxic adenoma	35	5.6
Total	630	100

The mean age of patients with solitary toxic adenoma was 49·7 (±13·4 s.d. years) with a range of 24–76 years. The mean age of patients with solitary non-toxic adenoma was younger, at 41·8 (±13·7 s.d. years) and a range of 13–78 years.

The maximum incidence of solitary toxic adenoma was in the decade 50–59 years (11 of 35 cases), whereas that of solitary non-toxic adenomas was in the 30–39-year period (30 of 135 cases) (*Fig.* 1). A 2 × 2 contingency test dividing the two groups at age 45 years shows this to be a significant difference ($P < 0·001$). In contrast, the mean age of patients undergoing surgery for Graves's disease (toxic hyperplasia) was 31·5±9·4 years (range 15–67) and that for toxic multinodular goitre 43·9± 13·7 years (range 15–78).

The sex incidence of toxic adenoma did not differ significantly from that of the other types of thyrotoxicosis or thyroid carcinoma. Of the cases of solitary toxic adenoma, 94·3 per cent were female, compared with 81·5 per cent for solitary non-toxic adenoma. Among patients with other conditions undergoing thyroid surgery the female incidence was 88·4 per cent for Graves's disease, 87·8 per cent for toxic multinodular goitre and 80·4 per cent for carcinoma.

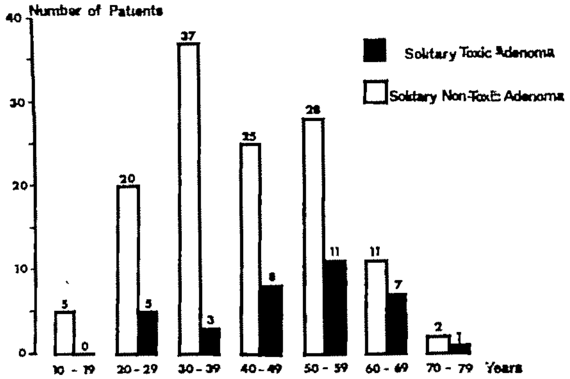

Fig. 1. Age incidence of solitary toxic adenomas and solitary non-toxic adenomas by decades.

Clinical features

The presenting complaint in 19 (54·3 per cent) of the 35 solitary toxic adenoma cases was the thyroid nodule itself. In 13 of these it had been present for 1 year or more, 2 patients claiming to have had a goitre since adolescence. A 53-year-old woman gave a 13-year history of a slowly enlarging lump in the neck, which had on two occasions been associated with toxicity and treated by radio-iodine. Despite this, the nodule had continued to enlarge and she came to surgery for pressure symptoms. In contrast, one patient presented with a 5-week history of a thyroid nodule first noticed after an upper respiratory tract infection, and slight symptoms of toxicity.

Only 13 cases (37·1 per cent) presented with symptoms of thyrotoxicosis. Irritability and anxiety predominated in 5, the symptoms being present for between 1 and 13 years. Three patients presented with weight loss, 3 with cardiovascular complications (one being diagnosed by her practitioner after a one-day episode of faintness and sweating) and one with menstrual irregularity. In 3 patients the toxic adenoma was found incidentally during the investigation of pulmonary, dermatological and arthritic problems. However, nearly all the patients had thyrotoxic symptoms on inquiry, sometimes only mild or intermittent, and these had often been present for many years.

Clinical examination revealed a solitary nodule in 18 (51·4 per cent) patients. In a further 9 cases a unilobar thyroid enlargement was noted, and in these cases at surgery the adenoma was found to occupy the major portion of one lobe. Four patients were thought to have a diffusely enlarged thyroid, 2 a multinodular goitre, 1 a retrosternal goitre and 1 a normal thyroid gland. The thyroid status was frankly toxic in 15 patients (42·9 per cent) and mildly toxic in 13 (37·1 per cent), whilst 7 (20·0 per cent) were thought to be euthyroid. Cardiovascular complications were present in 6 patients (17·1 per cent), 4 being in atrial fibrillation and 2 in congestive failure, their mean age being 63·5±4·8 years (range 56–69) compared with a mean age of 49·7 years for the group as a whole.

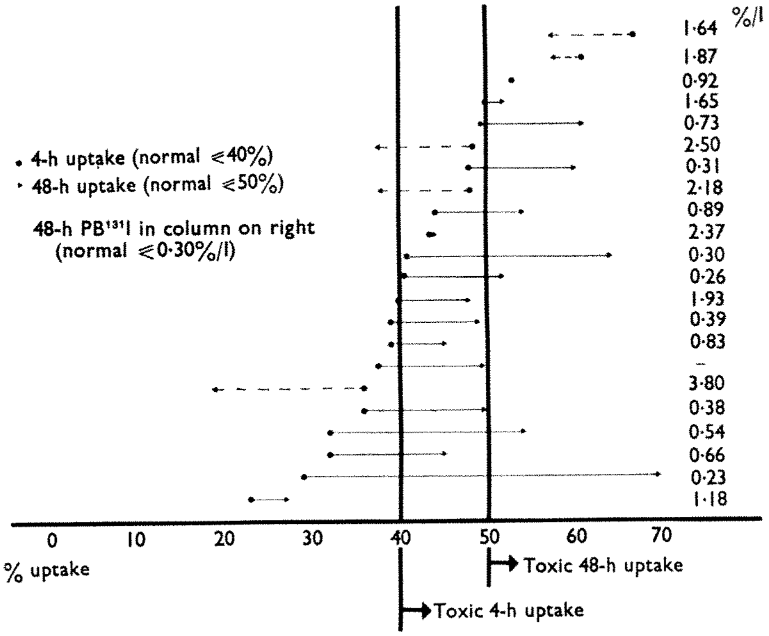

Fig. 2. Results of radio-iodine uptake tests in solitary toxic adenomas.

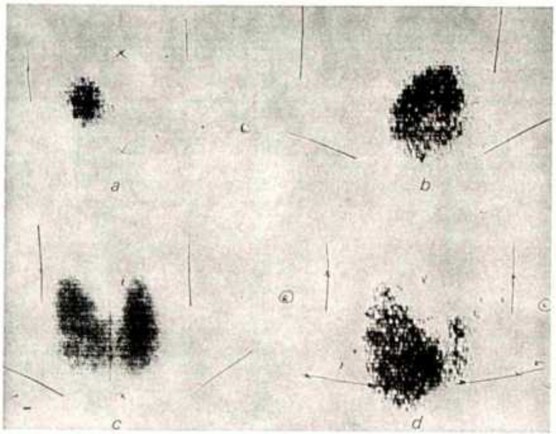

Fig. 3. Thyroid scans. *a*, Small 'T_3-toxic' adenoma in the right lobe. *b*, Large T_4 adenoma replacing left lobe. *c*, Graves's disease. *d*, Toxic multinodular goitre.

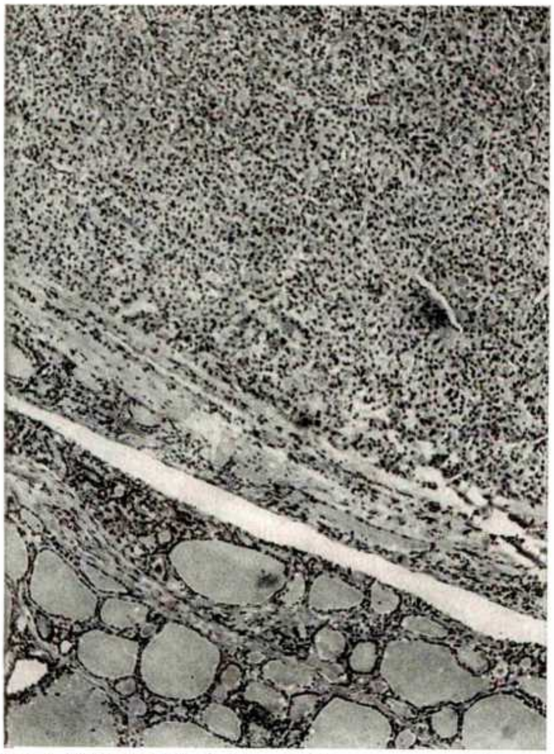

Fig. 4. 'Microfollicular' adenoma. Homogeneous cellular structure of the adenoma, separated by capsule from compressed normal thyroid follicles in the lower part of the field. (HE. ×53.)

In the 7 patients with solitary adenomas who were clinically but not biochemically toxic, 5 complained of the thyroid nodule or its recent enlargement.

None of the toxic adenoma patients had exophthalmos, or any other eye signs.

Biochemical investigations

Over the 15-year period, protein-bound-iodine (PBI) was the basis of the biochemical diagnosis of toxicity, often in conjunction with an *in vivo* thyroidal ^{131}I uptake test and a T_3

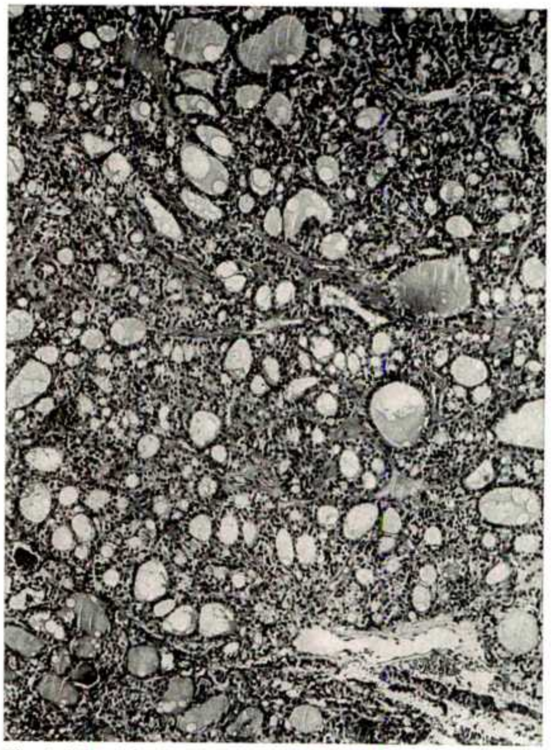

Fig. 5. 'Simple' adenoma. Structure resembles a normal thyroid gland. (HE ×53.)

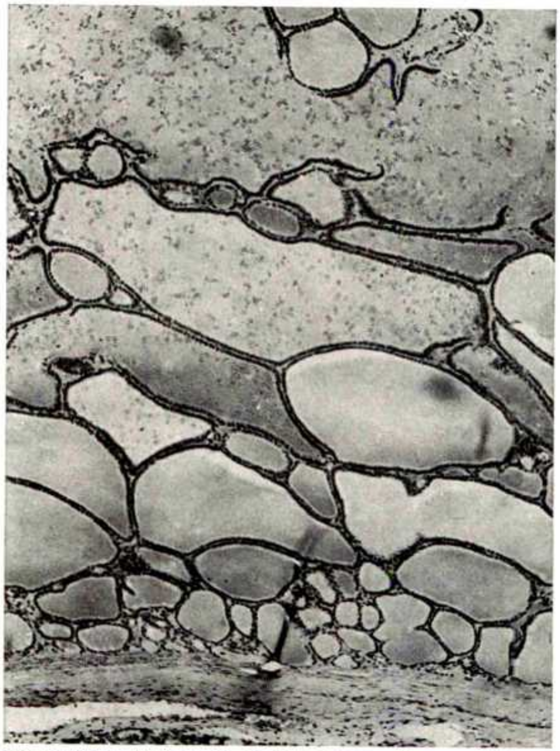

Fig. 6. 'Macrofollicular' (colloid) adenoma. Large colloid-filled acini separated by capsule from compressed normal thyroid below. (HE ×53.)

(tri-iodo-thyronine) resin uptake test, as described by Barnett et al. (1973) (*Table II*).

The mean PBI at the time of diagnosis of toxic adenoma was 0·77±0·14 s.d. μmol/l (range 0·53–1·19 μmol/l), the normal range being 0·30–0·63 μmol/l. Four patients had a PBI in the high normal range, at 0·60, 0·61, 0·62 and 0·62 μmol/l, associated with toxic values for the ^{131}I uptake test or T$_3$ resin uptake test.

The ^{131}I uptake test was performed in 22 patients and gave toxic levels at 4 h (over 40 per cent uptake) in 13 patients (59·1 per cent) and at 48 h (over 50 per cent uptake) in 10 cases (45·5 per cent) (*Fig.* 2). The 48-h PB^{131}I was at a toxic level (over 0·30 per cent/l) in 19 cases (86·4 per cent), mean 1·19± 0·94 per cent/l, range 3·80–0·31 per cent/l).

Two patients had elevated T$_3$ levels at 4·69 nmol/l and 6·90 nmol/l (normal 1·23–3·07 nmol/l). In the first of these the thyroxine (T$_4$) was also raised at 182 nmol/l (normal 60–170 nmol/l). In the second T$_4$ was normal at 112 nmol/l, and this case is the only proved 'T$_3$-toxic' solitary adenoma in the series, but the T$_3$ and T$_4$ assays only became available in the last year of the survey.

Radioisotope scanning

Radio-iodine scanning commenced in the second year of this survey and was superseded by pertechnetate scintiscans for the latter 7 years. A total of 6967 thyroid scans was reviewed and 155 images suggestive of solitary 'hot' lesions identified in patients from the Sheffield Royal Infirmary. Thirty patients proved to have a solitary toxic adenoma (*Fig.* 3). The additional 5 in the series did not have scans, but their thyrotoxicosis was cured by lobectomy and was presumed to be due to the contained adenoma. A further 21 solitary autonomous toxic nodules arose within a multinodular goitre.

Pathology

The strict histopathological criteria of Meissner and Warren (1969) were applied before a solitary lesion was accepted as an adenoma. A well-encapsulated solitary nodule with a structure differing from that of the adjacent compressed normal gland was considered a true adenoma. The presence of two or more nodules usually indicated an area of multinodular goitre rather than an adenoma. Seventeen solitary toxic nodules due to multinodular goitre were excluded from the series. Solitary adenomas within toxic multinodular goitres were also excluded. Adenomas were subdivided into the cellular, relatively poorly differentiated, 'microfollicular' variety (*Fig.* 4), with minimal colloid or acinar structure, 'simple', well-differentiated adenomas whose structure approximated to that of the normal gland (*Fig.* 5), and 'macrofollicular' (colloid) adenomas with greatly distended acini containing excessive colloid (*Fig.* 6). Hürthle cell adenoma, derived from variants of follicular cells with excessive and abnormal mitochondria, was the final category recognized. There was considerable variation of histological pattern within each adenoma, limiting the value of such subdivisions.

Twenty-two of the 35 solitary toxic adenomas (62·9 per cent) were of the relatively cellular microfollicular and simple varieties. In contrast, 83 of the 130 non-toxic solitary adenomas (63·8 per cent) were of the macrofollicular variety (*Table III*).

Degeneration, either visible grossly or microscopically, involving one-third or more of the adenoma was seen in 11 solitary toxic adenomas (31·4 per cent) and in 83 solitary non-toxic adenomas (63·8 per cent) (*Table III*, *Fig.* 7).

A focus of papillary carcinoma was identified in one toxic macrofollicular adenoma. Possible malignant change was also seen in one macrofollicular adenoma from a patient clinically, but not biochemically, toxic.

Surgical management

Unilateral thyroid lobectomy has been the policy throughout the 15 years. Thyrotoxicosis was controlled with carbimazole, usually commencing with 15 mg strictly 8-hourly and then reducing as the patient became euthyroid. Preoperative therapy with potassium iodide was not regarded as necessary in this condition, and in this unit it is no longer used preoperatively in any type of thyrotoxicosis. If at operation the solitary nodule was confirmed, the opposite lobe was inspected but otherwise not disturbed, thereby eliminating the risk of postoperative hypoparathyroidism. Identification of the recurrent laryngeal nerve was routinely performed and parathyroid gland identification attempted. Wound management was facilitated by a suction drain and Michel clips, both being removed 2 days postoperatively. The usual hospitalization period was 4–5 days.

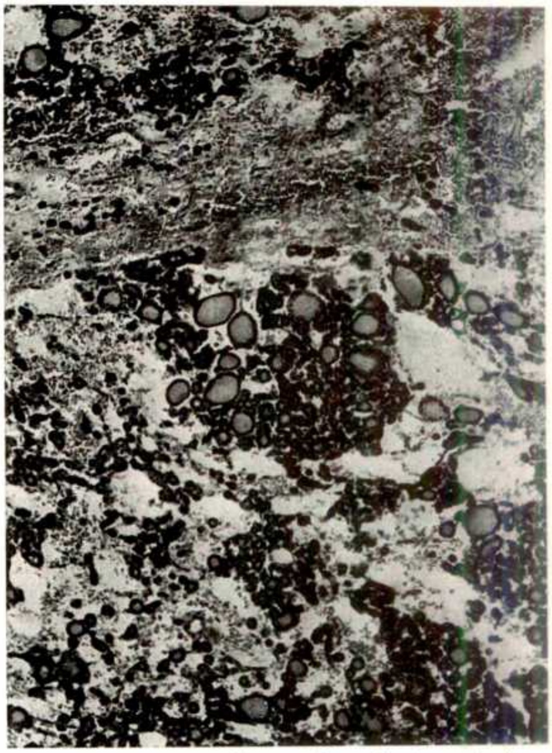

Fig. 7. Degeneration and haemorrhage affecting a simple adenoma. (HE ×53.)

Table III: HISTOLOGICAL DATA

Histological variety	Solitary toxic adenoma	Solitary non-toxic adenoma
Microfollicular	5 (14·3)	15 (11·6)
Simple	17 (48·6)	30 (23·2)
Macrofollicular	13 (37·1)	83 (63·8)
Hürthle cell	0	2 (1·4)
Haemorrhage and degeneration	11 (31·4)	83 (63·8)

Figures in brackets are percentages.

Results

Following unilateral thyroid lobectomy in the 35 patients with solitary toxic adenoma, there was no operative mortality and no significant early postoperative morbidity. After a mean follow up of 6·3± 3·9 (s.d.) years (range 0·5–15), 30 patients (85·7 per cent) remain euthyroid clinically and biochemically. Five patients (14·3 per cent) have become hypothyroid. This was detected in 2 cases 1 month postoperatively, in a further 2 cases at 3 and 8 months respectively and in 1 case at 18 months. Five other patients have developed varied conditions. Two cases of depression occurred at 4 and 11 months postoperatively, a single fatal case of breast carcinoma in a euthyroid patient 5 years postoperatively and single cases of disseminated sclerosis and senile dementia several years postoperatively.

The further 7 patients with solitary adenoma, clinically but not biochemically toxic, have all remained euthyroid following lobectomy.

Discussion

Clinical features and difficulties in diagnosis

Henry Plummer (1913) first differentiated toxic adenoma from exophthalmic goitre, and it has remained a rare but interesting cause of thyrotoxicosis (Cope et al., 1947; Roualle, 1949; Montgomery and Welbourn, 1975). This survey establishes an incidence of 5·6 per cent for solitary toxic adenoma amongst thyrotoxic cases managed surgically in an area with a high goitre incidence.

The often mild toxicity and absence of eye signs may make the diagnosis elusive. Prolonged mental and physical ill health may result. Nineteen patients (54·2 per cent) complained of irritability and anxiety, often of some years' duration, whilst 6 patients (17·1 per cent) developed cardiovascular complications, emphasizing the dangers of the missed diagnosis. Ramsay et al. (1972) suggested that the adenomas may secrete to toxic levels only intermittently. The occurrence of degeneration accompanied by regeneration in adjacent areas in one-third of the toxic adenomas might explain this.

In the hyperthyroid patient the solitary 'hot' area on a scan is the key to diagnosis (*Fig.* 3), radioisotope uptake in the remainder of the thyroid being suppressed. Repeated evaluation of T_4 and T_3 levels may be required in suspect cases to confirm toxicity biochemically. It is of interest that in the single example of a 'T_3-toxic' adenoma in this series, the PBI was normal at 0·53 μmol/l. Possibly some of the patients with toxic symptoms but a normal PBI had 'T_3-toxic' adenomas before the T_3 assay became available. The value of the ^{131}I uptake test, especially the 48-hour $PB^{131}I$, which was elevated in nearly all those tested, is diminished by the findings of Fellinger et al. (1961) that the 48 hour $PB^{131}I$ is raised in most cases of hyperactive nodules regardless of whether the patient is toxic. The autonomous nature of the adenoma may be demonstrated by a scan after administration of thyroid-stimulating hormone and by its continued uptake of iodine in the T_3 suppression test. This test, however, has dangers in the elderly in whom cardiac dysrhythmia may be precipitated, and it is no longer necessary now that the thyroid-releasing hormone test is available.

Advantages of surgical management

The solitary toxic adenoma, with its high iodine avidity in an otherwise suppressed gland, seems the perfect candidate for radio-iodine therapy. Yet 4 of the 35 toxic adenomas managed surgically had failed to respond to radio-iodine. The ^{131}I uptake data (*Table II*, *Fig.* 2) indicate a fast uptake into a small iodine pool with rapid turnover (Fellinger et al., 1961; Ramsay et al., 1972). In 5 cases the 48-h uptake was already lower than the 4-h uptake, and the 48-h $PB^{131}I$ was markedly elevated. Structurally, these 5 adenomas were the more cellular microfollicular and simple varieties with little colloid storage. This rapid uptake, metabolism and release of radio-iodine implies that it might not remain within the adenoma long enough to be therapeutically effective.

In contrast, surgery rapidly controlled the thyrotoxicosis and was relatively complication-free. It was anticipated that the suppressed lobe would recover and the patient remain euthyroid. This failed to occur in 5 cases (14·3 per cent). The non-adenomatous tissue in the rest of the excised lobe appeared normal with no evidence of significant thyroiditis. Two patients had had prolonged antithyroid therapy before surgery—two courses of radio-iodine in one patient and carbimazole for 10 years in another. Presumably, the remaining lobe was functionally impaired, and both patients became hypothyroid immediately postoperatively, although Michie et al. (1972) and Pegg et al. (1973) demonstrated no correlation between antithyroid drug therapy and postoperative hypothyroidism.

In a further case the residual lobe was noted to be very atrophic and hypothyroidism developed 3 months postoperatively. Prolonged antithyroid therapy or a very small contralateral lobe might therefore be indications for a lesser excision than complete lobectomy. Two patients with normal residual lobes became hypothyroid at 8 and 18 months postoperatively. Careful postoperative follow-up is essential. Blum et al. (1975) managed 6 cases by excision with no postoperative hypothyroidism. In contrast, Molnar et al. (1965) reported 3 cases of postoperative hypothyroidism out of 11 toxic nodules managed surgically, 2 of the hypothyroid patients having undergone subtotal thyroidectomy. Three of the patients in our series were treated as hypothyroid on biochemical evidence early in the postoperative period. We would prefer to withhold thyroxine and accept minor clinical features of hypothyroidism with reduced thyroid hormone levels for some months. In our experience, such patients recover presumably due to reactivation of the residual lobe by endogenous thyroid-stimulating hormone.

A further advantage of surgery is indicated by the patient whose toxic adenoma contained a focus of papillary carcinoma, and the other patient with a possibly malignant area in a 'hot', clinically toxic adenoma. 'Hot' nodules on scan are held to be rarely malignant (Wade, 1975; Editorial, 1977). Johnston (1975) warns of a 4 per cent malignancy rate in 'functioning nodules' and Hamburger (1975) found 3 cases of coexistent carcinoma in 29 patients with 'autonomously functioning thyroid lesions', one being a focus of papillary carcinoma in a solitary toxic lesion. Lobectomy with follow-up is adequate management for the unsuspected papillary carcinomas in this situation (Johnston, 1975).

Management of autonomous adenoma not provenly toxic

Proponents of a conservative policy argue that the probability of a 'hot' nodule becoming toxic is low (Langarten and Spencer, 1973). In some cases degeneration and self-cure may ensue (Miller and Block, 1968), such changes being detected on serial ultrasound or radioisotope scans. However, the prolonged duration of symptoms in many cases of toxic adenoma in this series does not support this idea.

Certainly, degeneration was seen in one-third of the solitary toxic adenomas and in nearly two-thirds of the solitary non-toxic adenomas. However, this is one phase in a cycle and is likely to be followed by regeneration. The age distribution of toxic and non-toxic adenomas suggests a trend towards development of toxicity with time rather than the reverse.

In this series, 7 symptomatic patients with solitary autonomous adenomas who were clinically but not biochemically toxic were managed by lobectomy. All have remained euthyroid. It is notable that in 5 patients it was the thyroid nodule or its recent enlargement which was the main complaint. Lobectomy provides a rapid resolution of the patient's problem and the doctor's dilemma.

A case of craniocleidal dysostosis presenting with vascular complications

D. W. SHORT*

SUMMARY

A case of craniocleidal dysostosis was presented. In spite of the skeletal abnormalities present, the disease was not diagnosed until the patient, a married woman of 63, developed ischaemia of her right upper limb, followed by cerebral symptoms. An arch aortogram demonstrated an occlusion of the first part of the right subclavian artery involving the origin of the vertebral artery and a post-stenotic dilatation of the left subclavian artery due to costoclavicular compression. Such vascular abnormalities have not been previously described in this condition.

CRANIOCLEIDAL dysostosis is a relatively rare congenital condition in which there are skeletal and other anatomical abnormalities due to errors in the primary ossification of certain bones.

According to Abram (1907), the first description of the disease as a pathological entity was by Marie and Sainton (1898) who studied two affected families. In one family the disease was transmitted from the father to the son; in the other family the transmission was from mother to daughter. They named the disease 'la dysostose cleido-cranienne héréditaire' and defined the syndrome as a hereditable condition characterized by aplasia of the clavicles and overdevelopment of the transverse diameter of the cranium, coincident with delay in the ossification of the fontanelles.

The consistent involvement of the clavicles is attributable to the fact that the responsible genetic defect involves primarily those bones ossified earliest in fetal life, and the clavicle takes precedence as it is the first bone to be formed in the body. Primary centres appear in the mid-portion of the clavicle during the 6th week of intrauterine life. (The next bone in the body to ossify is the vault of the skull in which primary centres of ossification appear between the 6th and 8th weeks of intrauterine life.) Other bones less frequently involved include the lateral arches of the spine, pelvis, hip joints and the bones of the hands and feet.

Structural abnormalities in the clavicle range from a localized osseous defect in one clavicle to total absence of both clavicles. Usually when both clavicles are severely affected other gross anatomical defects are also present. The apex of the thorax is narrowed with the upper ribs drooping downwards and forwards with apparent lengthening of the neck (*Fig.* 1). The muscles normally attached to the clavicles may be vestigial, absent or have anomalous ligamentous attachments. The scapulas are frequently abnormal, being small, triangular in shape and more mobile than usual. In some cases the scapulas fail to articulate with the lateral remnants of the clavicle. It may be that most of these structural abnormalities are secondary due to faulty moulding consequent upon the collapse of the shoulder-girdle at a very early stage in the development of the fetus.

Soule (1946) found from a review of the literature that in a total of 323 cases, 198 were familial while 125 cases were sporadic. Both sexes were affected to an approximately equal extent, and the condition was transmitted through either parent with about equal frequency. According to Lasker (1946) the disorder is an autosomal dominant inheritance with the isolated cases being due to the frequent occurrence of a dominant mutation.

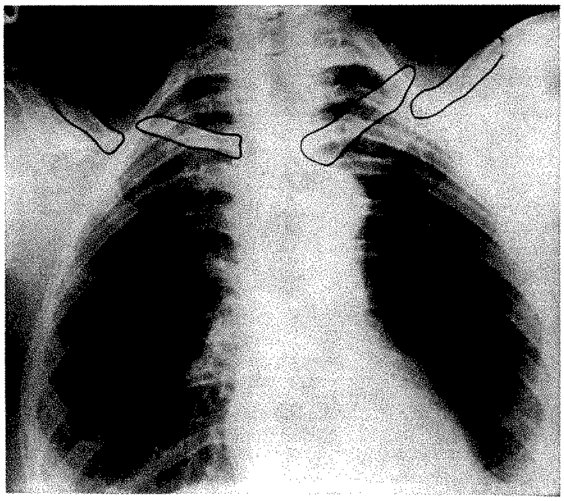

Fig. 1. Chest X-ray showing deformity of the upper thorax and the position of the clavicular fragments.

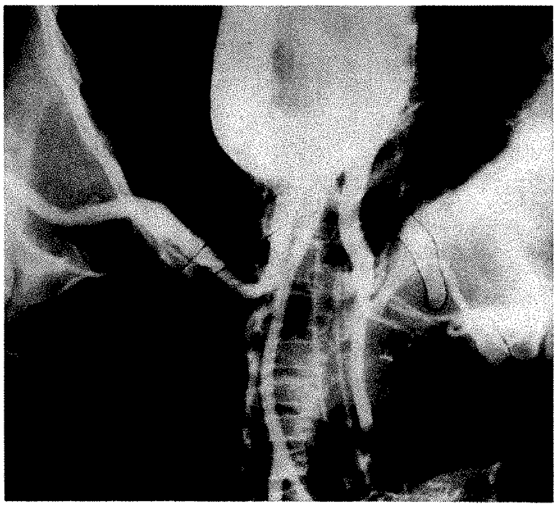

Fig. 2. Arch aortogram showing proximal occlusion of the right subclavian artery, involving the origin of the right vertebral artery. There is post-stenotic dilatation of the left subclavian artery.

Case report

Mrs H. M. knew since her childhood that she was 'double-jointed', in that she could approximate her shoulders and she was unaware of any other member of her family having had the same facility. Until 1966 she enjoyed reasonably good health. In 1966, at the age of 53, she developed recurrent attacks of chest pain which her doctor described as being 'atypical of angina'. She had also recently acquired a bruising tendency which was apparently spontaneous. She was referred to the medical outpatient clinic. On examination she was normotensive. An ECG tracing was reported as showing 'a degree of posterior myocardial ischaemia'. A full haematological assessment showed no abnormality to account for the bruising. She did not have a chest X-ray. No further appointment was made.

In 1975, at the age of 63, she was referred to the surgical outpatient clinic with a history of having developed, during a 'flu-like illness 2 weeks before, sudden and severe ischaemia of her right arm. When seen at the clinic, the right upper limb was ischaemic. The subclavian pulse on the right side was normal, but pulses distal to this were absent. The pulses on the left side were normal. Both femoral pulses were present. An ECG was reported as 'showing recent myocardial ischaemia'. An X-ray of the chest was reported as 'showing narrowing of the thorax. Both clavicles are hypoplastic with pseudoarthrosis. The scapulas are abnormally placed and are triangular in shape. The findings are consistent with cranio-cleido-dysostosis'.

A diagnosis of axillary embolism, probably cardiac in origin, was made. As the condition had stabilized and there had already been a degree of spontaneous improvement in the circulation to the right hand, surgical intervention was not considered and the patient was allowed home.

In June 1977 she was admitted to a medical ward with a cerebrovascular incident, having the features of acute vertebral–basilar ischaemia. The symptoms recovered spontaneously after a period of bed rest. ECG and cardiac enzymes were normal. It was noted that the right subclavian pulse which had been present at the previous examination was now absent. An arch aortogram (*Fig.* 2) was performed and showed the following:

Right subclavian artery: There was thrombotic occlusion of the first part of the subclavian artery which apparently also involved the origin of the left vertebral artery, which was not visualized at any phase of the aortogram. Only in the late films was there any trace of the contrast medium in the axillary and brachial arteries.

Left subclavian artery: The left subclavian artery was compressed between the first rib and the proximal portion of the left clavicle with a large post-stenotic aneurysm which was both elongated and kinked. There was no filling defect in the aneurysm suggestive of a mural thrombus.

After complete recovery from her cerebral symptoms the patient was allowed home to return at a later date. She had no recurrence of her cerebral symptoms and her only complaint was of continued discomfort and loss of power in her right hand.

At operation the neck was explored through bilateral supraclavicular incisions. On the *right side* the anatomy of the posterior triangle of the neck was grossly distorted by the deformity of the upper ribs and the deflections of the clavicular fragments. The scalene and other muscles in the posterior triangle were vestigial and difficult to identify, as was also the phrenic nerve. Occlusion of the first part of the subclavian artery was confirmed as was the absence of pulsation in the right vertebral artery. An upper dorsal sympathectomy was impracticable for anatomical reasons, and the wound was closed.

On the *left side* the anatomy was similar except that the subclavian artery was compressed between the first rib and the proximal fragment of the clavicle with post-stenotic dilatation of the left subclavian artery. Removal of the proximal fragment of the clavicle relieved the proximal arterial stenosis. The subclavian aneurysm was not resected.

Discussion

Craniocleidal dysostosis is uncommon, and despite the seemingly obvious presence of cranial and clavicular abnormalities, the condition is often not recognized until adult life. Affected persons have a normal expectation of life, and most are healthy, intelligent and capable of hard physical labour (Lasker, 1946).

Soule (1946) concluded from his review that the clavicular defects were of little or no significance as far as function was concerned, for those involved rarely complained of difficulty in using their arms or shoulders, whether taking part in manual work or in sporting activities. He cites the example of one of his patients, a baggage master, who was able to handle heavy trunks and crates without difficulty. Maddox (1946) quotes a similar experience with a stoker in the Royal Australian Navy during World War II. Davis (1954) had a patient who, retrospectively, credited to this anomaly his exceptional ability as a college wrestler to 'wriggle out of any hold'.

Lasker (1946), in a carefully documented survey of over 500 cases collected from the world literature, found only 2 examples of cases in which significant neurological or vascular symptoms had been present.

1. Jones (1937) reported the case of a girl born of normal parents whose only skeletal defect was bilateral pseudoarthrosis of her clavicles. At the age of 17 she complained of pain along the inner aspects of both arms when carrying heavy objects. At a subsequent operation, the clavicles were stabilized by insertion of bone grafts between the two fragments of each clavicle. The graft on the left side was successful with relief of symptoms; the graft on the right side failed owing to sepsis, and the graft had to be removed. She continued to have symptoms when this shoulder was depressed. She subsequently married, and had a son with the classic features of craniocleidal dysostosis.
2. Poynton and Davies (1914) had a patient with craniocleidal dysostosis. She was a girl of 20, who was unable to work as a dressmaker because of shooting pains down the inner side of her right arm and over the front of her chest. On examination, there was marked loss of power in her right hand, and when the shoulder was depressed the radial pulse was diminished. At operation, the outer fragment of the right clavicle appeared to be pressing on the brachial plexus, and it was therefore removed. This gave dramatic relief of her acute symptoms although she continued to have some discomfort in her shoulders when sitting over her work. This was relieved by sitting up and bracing her shoulders.

It is relevant to note that both these patients were young women at an age when costoclavicular symptoms related to posture are not uncommon amongst otherwise healthy females.

In spite of the very large number of cases of craniocleidal dysostosis scrutinized by Lasker and others, there is no reference to pathological lesions of the subclavian arteries, whether aneurysmal or occlusive, which might be attributable to the costoclavicular anomalies present. The case presented here is unique in this respect.

Spontaneous rupture of the normal spleen: diagnosis by computerized tomography

DAVID BIRD, M. J. KELLY AND R. N. BAIRD*

> So contrary is it to the established conceptions of pathology, that there are many who doubt that a normal spleen can rupture spontaneously.
>
> Hamilton Bailey (1930)

ATKINSON (1874) described the first case of spontaneous rupture of the normal spleen, and reports of this rare condition appear sporadically. We report here a case which was diagnosed preoperatively by computerized tomography (CT).

Case report

A 55-year-old housewife presented in December 1977 with a 3-week history of left hypochondrial pain of acute onset, which radiated to the back and left groin. She said there was a 'cricket ball' under her left lower ribs. Apart from minor urinary complaints there were no other symptoms. On this and subsequent occasions no history of trauma, however minor, was elicited. On examination there was a fixed, non-tender mass beneath the lower left ribs which was at this stage thought to arise from the left kidney or the spleen.

Investigations showed that haemoglobin, white blood count, platelets, urea and electrolytes, liver function tests, urine and chest X-ray were normal. A soft tissue mass was seen on the plain abdominal X-ray and excretion urography showed medial displacement of the left kidney. A ^{99}Tc^{m} colloid liver and spleen scan was interpreted as normal. CT scanning showed 'a high-lying left kidney, beneath which was an enlarged spleen, the lateral part of which had a different absorption coefficient (i.e. appeared darker) suggesting a lateral subcapsular splenic haematoma' (*Fig.* 1).

Laparotomy confirmed these findings and the spleen, which contained a cricket-ball-sized subcapsular haematoma, was removed. Recovery was uneventful, and histological examination of the spleen showed no intrinsic abnormality. Subsequent review of the isotope scan suggested concavity of the lateral surface of the spleen, but the appearances had not previously been considered diagnostic.

Comment

The existence of such a condition as spontaneous rupture of the normal spleen has been denied. Orloff and Peskin (1958) reviewed 71 cases of alleged spontaneous rupture of the normal spleen and found that possible causes had not been excluded in 43 cases (61 per cent). However, in the absence of a history of trauma, perisplenic adhesions or abnormalities of the spleen, a case such as ours appears, as far as it is possible to ascertain, to be truly spontaneous.

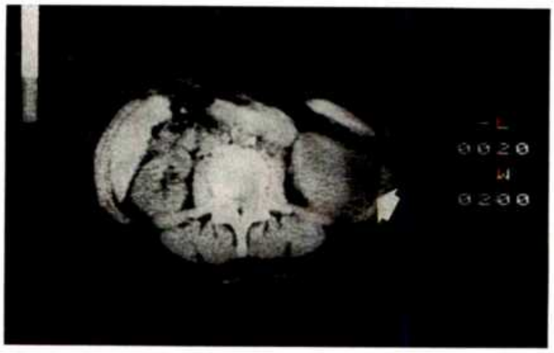

Fig. 1. Computerized tomography scan showing subcapsular splenic haematoma.

In the diagnosis of subacute splenic rupture ^{99}Tc^{m} colloid liver and spleen scanning may be unreliable (Budd et al., 1976), being unable to demonstrate defects smaller than 2 cm in diameter, or to demonstrate perisplenic structures including subcapsular haematoma of the spleen. Selective arteriography has been shown to be more accurate (Drapanas et al., 1969) but is a highly skilled invasive technique not without morbidity. In the present case the diagnosis was established by CT scanning, which we suggest may quickly and non-invasively provide valuable information in the investigation of suspected subcapsular splenic haematoma and thus lead to earlier definitive surgery.

Effect of levamisole on postoperative immunosuppression

Sir,

Cell mediated immunity is depressed following surgery (Cochran et al., 1972; Slade et al., 1975). A reduced lymphocyte responsiveness to phytohaemagglutinin (PHA) has been demonstrated in the first days after operation and this usually lasts 2–4 weeks (Roth et al., 1976). Immunodepression could conceivably contribute to the risk of metastatic diffusion and/or infections.

Our purpose was to determine whether levamisole, an orally effective modifier of the immune response (Tripodi et al., 1973), was able to reverse postoperative immunodepression.

In our study, based on 22 immunodepressed cancer patients, the lymphocyte response to PHA was evaluated 3 days (T_{-3}) and just before (T_0) operation and 2 (T_2), 4 (T_4) and 14 (T_{14}) days after operation. Eleven patients received one dose of 150 mg levamisole orally daily for 3 days between T_{-3} and T_0, and 11 patients were controls.

The results are summarized in the Table. In levamisole pretreated patients the lymphocyte response to PHA at times T_4 and T_{14} appears to be greatly increased compared with preoperative values. Furthermore, lymphocyte reactivity 4 and 14 days after surgery is significantly higher in treated than in control patients.

	LT	CO
T_{-3}	$4{\cdot}42 \pm 3{\cdot}75$	$2{\cdot}82 \pm 1{\cdot}60$
T_0	$2{\cdot}72 \pm 2{\cdot}19$	$2{\cdot}61 \pm 1{\cdot}13$
T_2	$2{\cdot}45 \pm 1{\cdot}55$	$1{\cdot}95 \pm 0{\cdot}53$
T_4	$5{\cdot}89 \pm 3{\cdot}32$*	$3{\cdot}29 \pm 1{\cdot}10$
T_{14}	$8{\cdot}44 \pm 4{\cdot}64$**	$3{\cdot}43 \pm 1{\cdot}86$

LT, Levamisole treated; CO, controls. Values are stimulation index $\bar{x} \pm$ s.d. Stimulation index = (mean count/min PHA stimulated cultures)/(mean count/min unstimulated cell cultures). Normal values >5.
* $P < 0{\cdot}02$ for T_0 *v.* T_4. ** $P < 0{\cdot}005$ for T_0 *v.* T_{14}.

Our data seem to agree with those of Windle et al. (1978), confirming that levamisole could reverse postoperative immunodepression. This may be of some importance in preventing early septic complications in postoperative care and cancer cell dissemination after a surgical procedure.

Talc on surgeons' gloves

Sir,

We would like to correct a misconception which appears to have arisen from our original paper in your journal entitled 'Identification of talc on surgeons' gloves and in tissue from starch granulomas', **62**, 941–944. Two subsequent papers in your journal, namely 'The significance of starch powder contamination in the aetiology of peritoneal adhesions' (Cooke and Hamilton, **64**, 410–412) and 'Talc granuloma of the ureter: a case report' (Joannides, **65**, 883–885) have both drawn an incorrect conclusion from our paper. It has been suggested that we reported that talc contamination occurs during the preparation of Bio-sorb. We have examined numerous sachets of Bio-sorb which are included with the surgeons' gloves and also samples from bulk material which would be used as a dusting powder for releasing the rubber gloves from their moulds; in none of these samples have we encountered talc. The talc particles which were identified on the surface of the UK-manufactured surgeons' gloves were from accidental contamination, which has now been corrected. The large number of talc particles observed on certain American-produced surgeons' gloves, on occasions in excess of 6×10^7 particles/cm^2, would suggest that it is this material that is being employed as the releasing dusting powder in the moulding process.

Book reviews

Radiologic Management of the Massively Traumatized Patient

Ayella. 280 × 220 mm. Pp. 297 + xvi, with 612 illustrations. 1978. Baltimore: Williams & Wilkins. $50.00.

Dr Ayella has put all those concerned with the care of the severely injured in his debt by producing this book, of which he has written 13 of the 16 chapters. The other three deal with computed tomography, ultrasound and nuclear medical methods of investigation. Apart from explaining in clinically well-informed, as well as radiological, detail a very wide range of methods of investigation, the author is at pains repeatedly to point out the dangers of unthinking resort to radiological investigation. In emphasizing the need to be content in many cases with rather poor portable films he also indicates how best to make use of what information is made available and what needs to be done to avoid errors of omission.

The fifteenth chapter on the extremities makes rather disappointing reading after the previous fourteen. It has few headings and omits a number of areas and subjects that are well-known causes of difficulty and confusion. In future editions I would like to see this section expanded and contain more advice about how to diagnose in good time the 'minor' injuries that may give the survivor of severe injuries his main lasting complaints.

The book is well produced but there are a few spelling mistakes, especially Le Forte, Fig. 15.119 is upside down and some of the X-ray films are of surprisingly poor quality.

P. S. LONDON

Operative Surgery

General Editors Charles Rob and Sir Rodney Smith. Third edition.

Accident Surgery

Edited Peter London. 282 × 220 mm. Pp. 600. Illustrated. 1978. Sevenoaks: Butterworths. £55·00.

One difficulty which faces the editors of all practical books on operative surgery is especially troublesome for the editor of a book on accident surgery. How to give sufficient detail to permit effective understanding of the principles and techniques of the operations, and yet not overcrowd the book with text and pictures so that it becomes a vast and unwieldy tome. This difficulty has been successfully surmounted by Mr Peter London in this volume on accident surgery in the *Operative Surgery* series. It is good to see a book so arranged that adequate information is displayed in a simple and uncomplicated fashion so that advice is easily available.

The many international contributors have produced a well-balanced book yet each chapter is sufficiently different in content and illustration to make refreshing reading for the trainee using the volume as a textbook of accident surgery.

Despite the general high standard of the text and illustrations, some sections do not entirely satisfy. The section on exposure of the arteries is obviously not written specifically for this book, and it is difficult to find advice in the section on the management of many common problems encountered in arterial trauma. I did wonder too if this book was the place for a discussion on the merits of single-layer gut anastomosis.

The section on liver injury is particularly good. It gives a very well-balanced view of the problem and provides advice and guidance on all aspects of this difficult and formidable injury.

This book fulfils a need long felt in accident departments and certainly should be available for reference in any operation theatre where major trauma is treated. It is sad that its price, like that of the other volumes in this series, puts the book virtually out of reach of most trainees, but nevertheless it is still worth the money.

H. JOHN

Lumbar Puncture and Spinal Analgesia

J. A. Lee and R. S. Atkinson. 222 × 145 mm. Pp. 214, with 108 illustrations. 1978. Edinburgh: Churchill Livingstone.

Some doctors believe that a medical anaesthetist is essential for successful surgery. Most anaesthetists like to think so, anyway. In fact, in large areas of the world, they are a luxury and anaesthesia may have to be administered by assistants or by the surgeon himself. In such circumstances, the value of a thorough, practical grasp of the technique of spinal analgesia is self-evident.

In the UK spinal and epidural anaesthesia are under-utilized in routine anaesthetic practice. This is due, in part, to the Woolley and Roe tragedies and, in part, to the great advance in general anaesthesia which followed the introduction of muscle relaxants. However, the principal bar to these techniques is the fact that they require more time in the anaesthetic room. It is in this context that one can unhesitatingly recommend this book to surgeons, for there is no doubt that it is when the surgeon appreciates the value to him of these techniques that any inconvenience caused by their employment is outweighed by their benefits. These benefits range from a reduction in bleeding, good relaxation and contracted gut, to better postoperative analgesia. This book shows how the benefits may be maximized and the disadvantages minimized.

Only a couple of pages are specifically directed at the single-handed surgeon: the remainder is clearly written for anaesthetists. And it is indeed clearly written—and clearly illustrated, attractively printed and carefully referenced. In consequence, the surgeon contemplating undertaking spinal anaesthesia could hardly find a better primer to set him on the right road. Surgeons working in the lower abdomen or on the legs should also be stimulated to try the influence of this type of anaesthesia on their practice.

Ancient Indian Surgery

Diagnostic Considerations, Volume 3

Edited G. D. Singhal, L. M. Singh and K. P. Singh 140 × 215 mm. Pp. 264 + xxiv. 1972. Allahabad, India: Singhal Publications.

Anatomical and Obstetric Considerations, Volume 4

Edited G. D. Singhal and L. V. Guru. 140 × 225 mm. Pp. 241 + L. 1973. Allahabad, India: Singhal Publications.

Toxicological Considerations, Volume 7

Edited G. D. Singhal and R. N. Dwivedi. 135 × 220 mm. Pp. 226 + xL. 1976. Allahabad, India: Singhal Publications.

A look into the past can occasionally make a welcome change in an era when reports on double blind trials and the like are numerous and only occasionally relieve the blindess of ignorance.

These three books, part of a series dealing with diagnosis, anatomy and toxicology, are a credit to the editor-in-chief, Dr G. D. Singhal of the Department of Paediatric Surgery at Banares University and his several co-editors. This English translation from Sanskrit of the great treatise of *Susruta Samhita*, a famous ancient Indian surgeon, presents an authentic scientific version of this outstanding classic.

Many subjects are covered including burns, lithotomy, piles, fistula, skin and eye diseases and are claimed by the editor to antedate many of the well-known classical descriptions.

It is a fascinating work and a valuable contribution towards our knowledge of world medical history. It is also a readable book with a compelling charm, especially so to those who have a first-hand knowledge of the Indian subcontinent. I personally enjoyed reading it.

QUESTIONS AND ANSWERS IN GENERAL SURGERY

H. P. HENDERSON, FRCS, *Senior Registrar, Plastic and Jaw Surgery, Fulwood Hospital, Sheffield;* and M. J. KELLY, MChir, FRCS, MRCP, *Senior Registrar in General Surgery, Bristol Royal Infirmary*

With a Foreword by The Right Hon. the Lord Smith of Marlow, KBE, MS, FRCS

This book contains questions and answers suitable for candidates revising for the Final FRCS Examination in General Surgery. The whole field for the examination is covered including subspecialties. The questions are laid out in random fashion to lessen the tedium of learning section by section and the answers have been placed adjacent to the questions. An index has been provided to enable readers to work through particular sections of their revision if they so wish

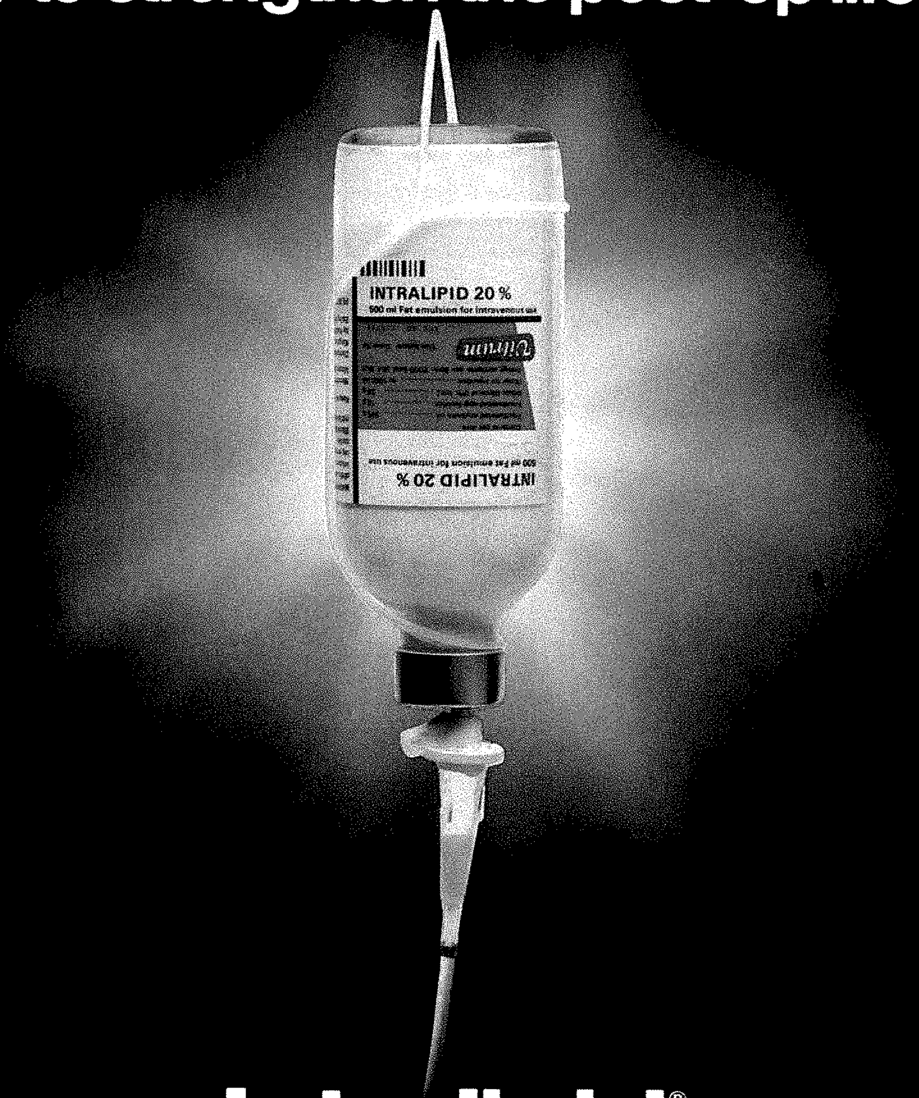
How to strengthen the post-op life line



INTRALIPID 20 %
500 ml Fat emulsion for intravenous use
Vitrum
INTRALIPID 20 %
500 ml Fat emulsion for intravenous use

Intralipid®

soya bean oil emulsion 10% and 20%

the most concentrated source of energy for central and peripheral infusions from the world leaders in complete intravenous nutrition

PRESCRIBING INFORMATION

INTRALIPID® 10% INTRALIPID® 20%

Presentation A milky-white oil in water emulsion

	Intralipid 10%	*Intralipid* 20%
Fractionated soya bean oil	50 g	100 g
Fractionated egg lecithin	6 g	6 g
Diluted glycerol (Ph. Int.)	12.5 g	12.5 g
Water for injections to 500 ml		

pH c. 7. The solution is sterile and pyrogen free.

Uses When feeding patients intravenously the possibility of providing a sufficient amount of energy in the form of carbohydrate is limited by such considerations as hypertonicity, hypervolaemia and the tendency to thrombophlebitis. The development of fat emulsions has overcome these problems. Fat has a high energy value (9.3 calories per gram) and by the use of fat emulsion it is possible to provide a high calorie intake in a relatively small fluid volume. Fat emulsions also have a protein-sparing effect when given in conjunction with amino-acid solutions to correct negative nitrogen balance. The intravenous fat emulsion Intralipid is metabolised in the same way and at the same rate as normal chylomicrons. One litre of Intralipid 10% provides 1,100 calories and 1 litre of Intralipid 20% provides 2,000 calories.

Indications. Intralipid fat emulsions are indicated in conditions of severe protein depletion requiring also a high energy intake to compensate for excessive loss of calories following trauma, infection, fever, burns, etc.

Dosage and administration Intralipid 10%: 500–1,500 ml daily in conjunction with intravenous amino-acids. For increased caloric requirements Intralipid 20%: 500–1,500 ml daily in conjunction with amino-acids. Intralipid 10% and 20% are administered by slow intravenous infusion. During the first 10 minutes the drip rate should be adjusted to 20 drops per minute and after half an hour this can be adjusted to a final rate of 60 drops per minute. 500 ml of either emulsion should be given in not less than three to five hours on the first day of infusion. On the first day of infusion it is advisable to administer 10 ml Intralipid 10% or 5 ml Intralipid 20% per kg body weight. Subsequently the dose is usually doubled, and when a larger intake is indicated it may be increased to 3 g fat per kg body weight.

Infant dosage. Intralipid 10% or 20%: 15–20 ml per kg body weight in 24 hours.

Contra-indications, warnings, etc. Intralipid is contra-indicated in pathological hyperlipaemia and severe liver damage.

Precautions. When daily intravenous fat administration for more than one week is indicated it must be ascertained, in order to prevent the development of cumulative lipaemia, that the patient is capable of eliminating the infused fat from the circulation, and this function can be tested in the following manner. In the morning following the first day's infusion, a citrated blood sample is drawn, preferably when the patient is still in a fasting state. The blood sample is centrifuged at 1,200–1,500 rpm. If the plasma is then strongly opalescent or milky, further infusion should be postponed. In the great majority of cases, plasma is completely clear 12 hours after the conclusion of an infusion of 2 g fat per kg body weight (corresponding to 20 ml of Intralipid 10% or 10 ml of Intralipid 20% per kg body weight). This test should be repeated at weekly intervals.

Pharmaceutical precautions Store at a temperature between 4°C and 8°C, and do not use after the date of expiry indicated. The contents of each bottle are for a single infusion and any residual emulsion should be discarded. No drugs should be added to Intralipid prior to or during infusion.

Legal category No legal restriction on sale or supply.

Package quantities *Intralipid 10%*: 100 ml and 500 ml. *Intralipid 20%*: 100 ml and 500 ml.

Further information Nil.

Whilst every effort is made by the publishers and editorial committee to see that no inaccurate or misleading data, opinion or statement appear in this Journal, they wish to make it clear that the data and opinions appearing in the articles and advertisements herein are the responsibility of the contributor or advertiser concerned. Accordingly, the publishers and the editorial committee and their respective employees, officers and agents accept no liability whatsoever for the consequences of any such inaccurate or misleading data, opinion or statement.

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, John Wright & Sons Ltd, Broadmead House, 21 Panton Street, London SW1Y 4DR.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the journal unless rights are reserved before publication.

Business communications should be sent to *John Wright & Sons Ltd, British Journal of Surgery, Bristol BS8 1EX.* Remittances are payable to the *British Journal of Surgery.*
Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

Manuscripts

The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations

It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978: **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors.* London, Pitman, 1978.

References

In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus.* Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).

- ✱ routinely used in more than 40 different surgical procedures
- ✱ pre-formed to direct pressure uniformly in the applier-true parallel closure without scissoring
- ✱ distal end closes first to encompass all the vessel
- ✱ available in four sizes

Hemoclip closure:
Left is the clip closed, providing a tenacious yet hypotraumatic grip.
Centre is the partially closed clip forming a ring. Right is the open clip; magnifying the longitudinal and transverse grooving-a milled, grooved surface that grips securely without slippage.

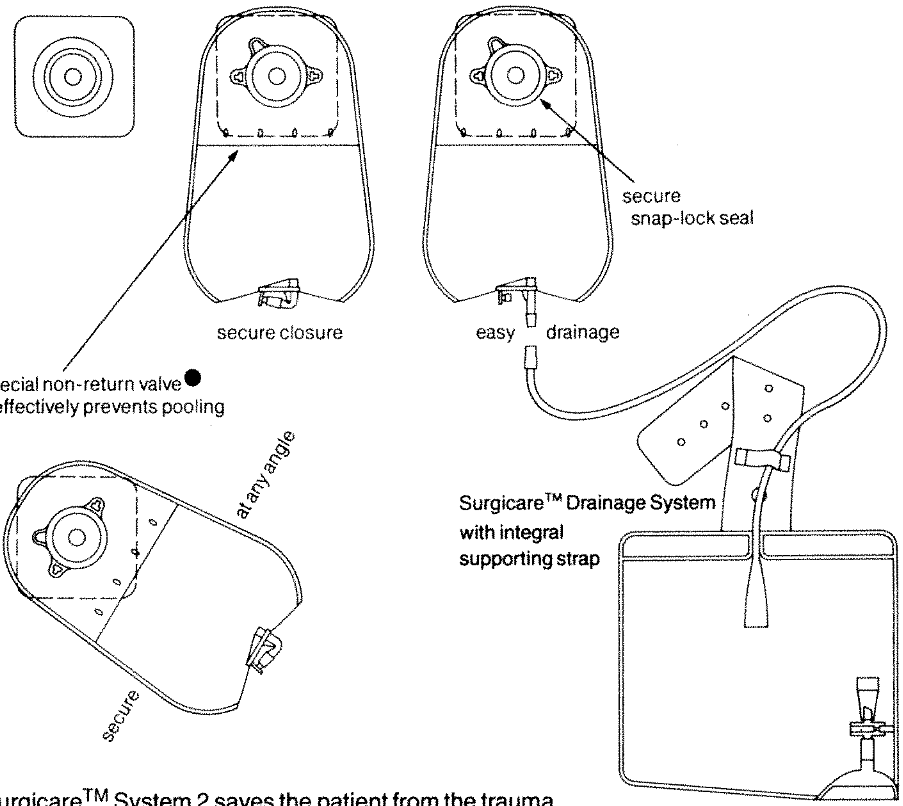
New for Urostomy!

a new standard of comfort and security

SURGICARE System 2

Trademark



Stomahesive™ Flange
the best in skin care
Urostomy pouches simply snap onto the Stomahesive™ Flange
secure
snap-lock seal
secure closure
easy drainage
special non-return valve ●
effectively prevents pooling
at any angle
secure
Surgicare™ Drainage System
with integral
supporting strap

Surgicare™ System 2 saves the patient from the trauma of peeling off adhesive bags. The Stomahesive™ Flange can be left on the skin undisturbed for several days whilst the pouches are replaced as often as necessary. It makes possible a leak-free attachment of appliances to the skin thereby providing a unique degree of comfort free of irritation and soreness often associated with ordinary adhesives. Surgicare™ System 2 takes full advantage of these benefits which are particularly evident in the management or urostomies.

● The non-return valve permits easy access of urine to the lower part of the pouch and efficiently prevents the return of urine to pool in the area of the stoma thus the Stomahesive™ wafer is protected from the breakdown effects of urine and remains secure and leak-free for several days.

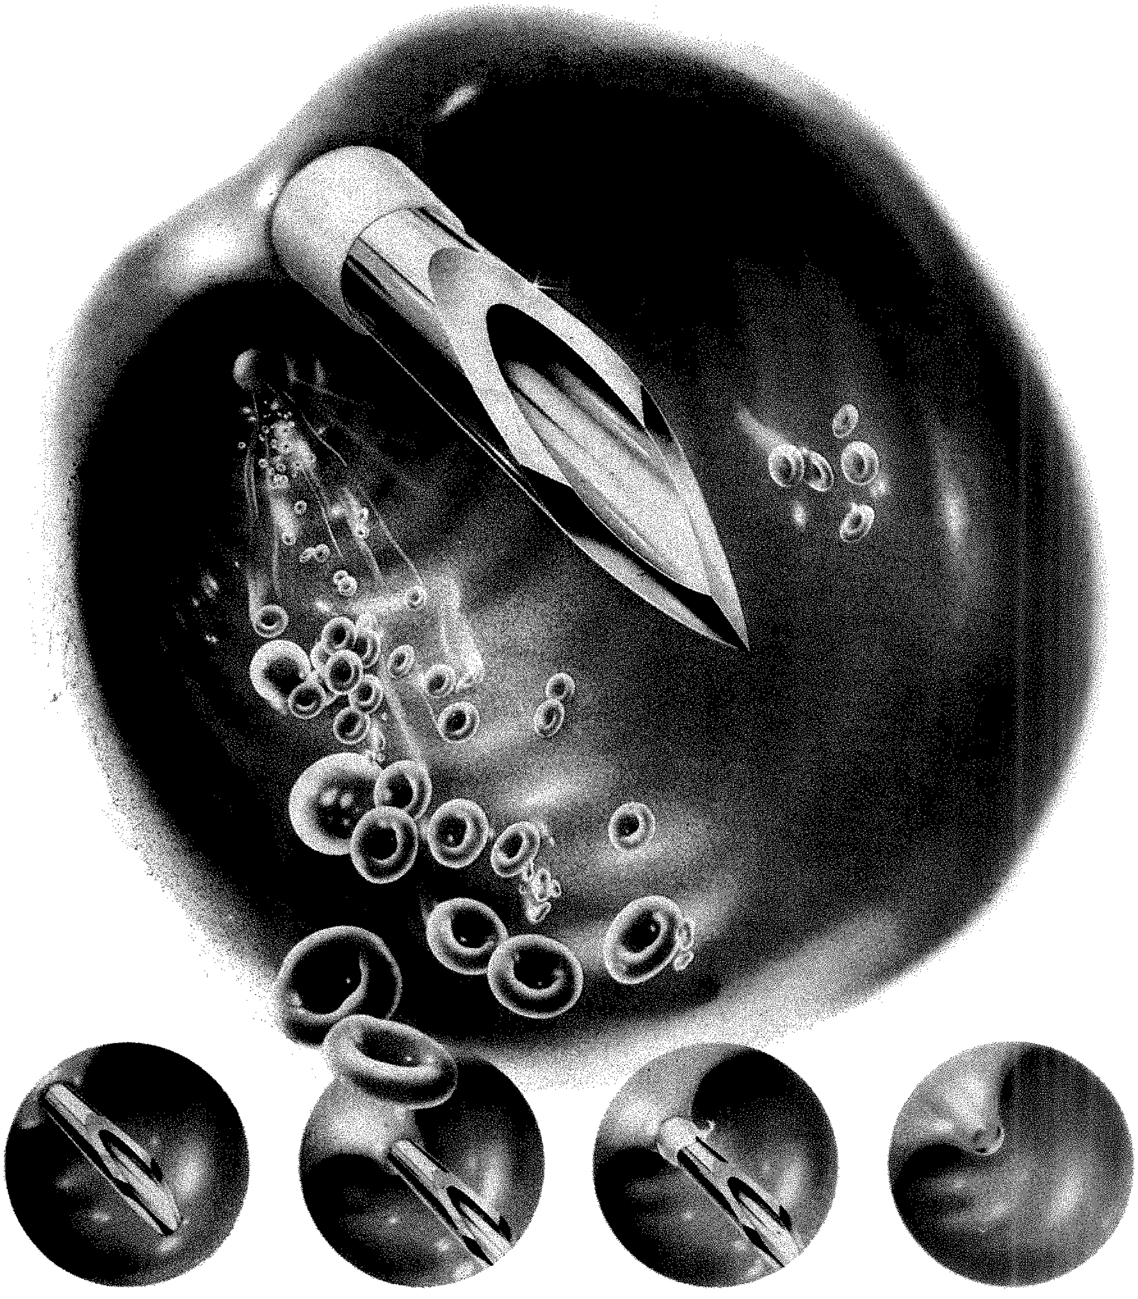
The intravenous difference



Where the distance between the cannula tip and the heel of the needle bevel is too great, there is a risk of piercing the opposite vein wall before the cannula is satisfactorily placed within the lumen. With Abbocath®-T, the cannula tip fits snugly behind the heel of the short bevelled needle tip.

An abrupt cannula shoulder requires a high penetration force, leading to tissue and vein trauma, discomfort, and repeat procedures. The electronically formed double taper tip of Abbocath-T requires a minimal penetration force which is constant from cannula to cannula.

A thin cannula shoulder is likely to curl back or shear during insertion, irritating the vein intima and increasing the risk of thrombus formation and phlebitis. The Abbocath-T cannula tip is smooth and sturdy, with no ragged edges or thin spots, and never protrudes over the heel of the needle.

The cannula is [illegible] lumen following [illegible] resulting in [illegible] infiltration of [illegible] Abbocath-T has [illegible] withdrawal.

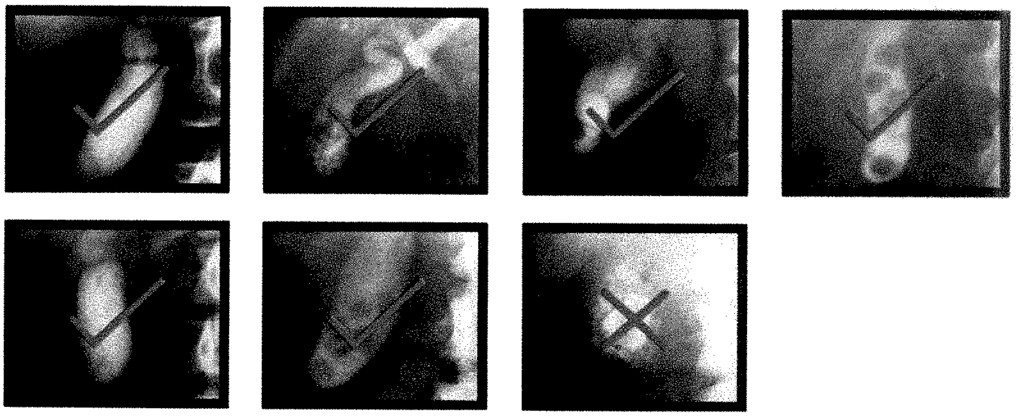
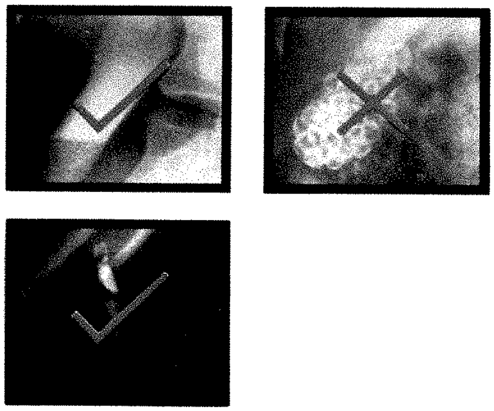
Chendol

What proportion of stones are suitable?





80%

Chendol can remove gallstones without surgery

Chendol solubilises 80% of all gallstones

CHENDOL acts on all mixed stones and cholesterol stones that are not calcium coated by reducing the amount of cholesterol secreted into the bile. Precipitated cholesterol is solubilised.

INDICATIONS For dissolution of gallstones. Cholesterol stones coated with calcium, or stones composed of bile pigments are not dissolved by chenodeoxycholic acid.

DOSAGE The present clinical evidence suggests that optimum results will be obtained on a dose level of 10–15 mg per kg. body weight daily in divided doses.

CONTRAINDICATIONS, WARNINGS, ETC. CHENDOL should not be administered to patients with radio-opaque calcified gallstones nor to patients with non-functioning gallbladders, nor to patients with chronic liver disease, nor with inflammatory diseases of the small intestine and colon.

CHENDOL should not be administered to women who may become pregnant.

Results of recent studies have demonstrated a 93% success rate in the U.K.[1] and 81% in the U.S.A.[2] for solubilising cholesterol rich radiolucent gallstones in suitable patients.

CHENDOL is generally well tolerated, the only side effects reported to date are diarrhoea and pruritus. It has been found that after a slight reduction in dose for a few days, diarrhoea ceases and the dose can then be gradually increased to the former level. Laboratory monitoring should accompany treatment.

Each CHENDOL capsule contains 125 mg of chenodeoxycholic acid.
Available in securitainers of 100 capsules – N.H.S. cost £13.50 per pack
500 capsules – N.H.S. cost £65.00 per pack

Universal Tube Holder

From Downs Surgical.

British Patent No 1 471 609
Designed by Laurence F Tinckler MD, ChM, FRCS, FACS.

For the fast, convenient and comfortable retention of a variety of tubes, catheters and leads used for patient treatment and diagnosis.

☐ **Fast:**
May be positioned immediately. Unique slot-in action ensures its easy application after tubes have been connected.

☐ **Convenient:**
Seven different slot sizes for retaining a wide range of tubes so that the risks of tension, kinking and occlusion are reduced. Tubes can be temporarily released to facilitate nursing procedures.

☐ **Comfortable:**
The flexible base conforms to most anatomical situations. Non-allergenic adhesive. Avoids the discomfort associated with bandages, strapping and anchor-suturing methods of tube retention.
The Universal Tube Holder is packaged in dispenser boxes of 25. Each Universal Tube Holder is double-wrapped and pre-sterilised by gamma irradiation. Catalogue reference BH 010-01-L.

Downs Surgical – simply the best

To: Disposable Products Division, Downs Surgical Limited, Church Path, Mitcham, Surrey, CR4 3UE, England.
Please send me further information and samples of the Universal Tube Holder.

Benign Breast Disorders

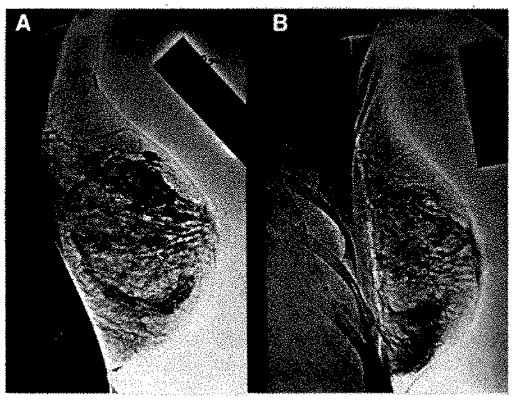
3 studies on Danol

1. "...a marked improvement in both objective and subjective symptoms in 87.5% of patients studied."

(Study of 40 patients given Danol for up to 6 months. Obstet. Gynec 1976, 48: 93.)

2. 75.8% "...experienced complete relief of subjective discomfort with disappearance of clinical signs."

(Study of 58 patients given Danol for between 74 and 310 days. Am. J. Obstet. Gynec. 1977, 127: 130.)



Xeromammograms of patient with intense fibrocystic disease (A) showing marked reduction in breast size and cystic area (B) after 6 months on Danol.

3. "...a significant decrease and elimination of breast pain and tenderness ...and elimination of nodules and lumpy areas..."

(Preliminary report on open study of 260 patients given Danol for 4 to 6 months. J. int. med. Res. 1977, 5 (Suppl. 3) 101-108.)

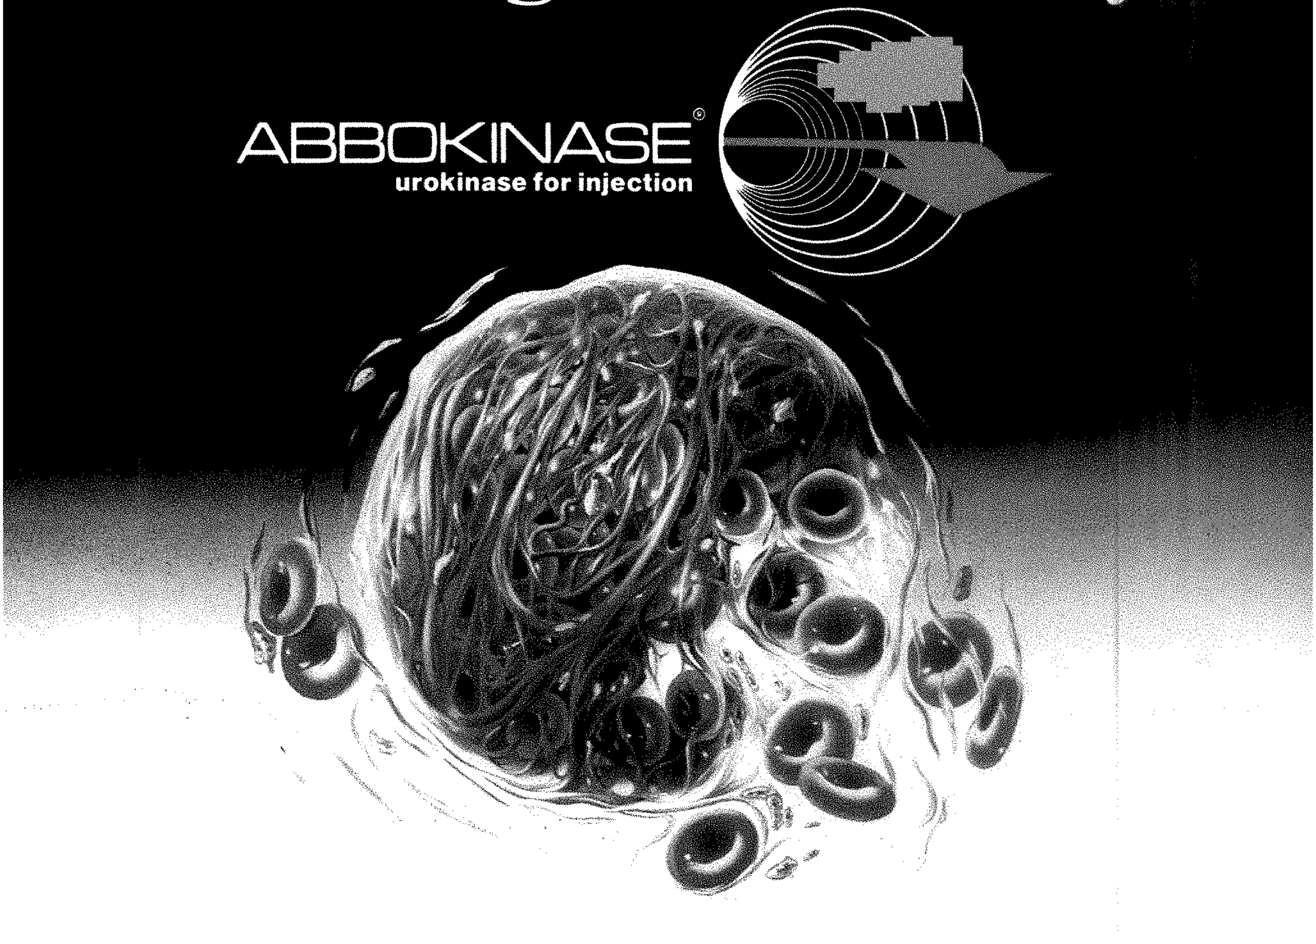
Danol
danazol

antigonadotrophic agent without oestrogenic or progestogenic activity

Danol (danazol 200 mg) PL 0071/0095. Bottles of 100 capsules. Basic NHS cost of one day's treatment £1 42 (3 capsules). **Danol-½** (danazol 100 mg) PL 0071/0094. Bottles of 100 capsules. Basic NHS cost of one day's treatment 72p (3 capsules). **Dosage** Adults 200-800 mg daily. See Data Sheet for details. **Contra-indications** Pregnancy. **Precautions** 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop. **Side Effects** Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control. Danol is a trade mark. Clinical reports and full prescribing information available on request from **Winthrop Laboratories,** Surbiton-upon-Thames, Surrey.

WINTHROP

Announcing the availability of



ABBOKINASE®
urokinase for injection

The first tissue-culture urokinase for the treatment of pulmonary embolism.

With significant advantages, both clinical and practical, over other thrombolytics, anticoagulant therapy and surgery.

- **Abbokinase achieves rapid clot lysis by a direct action on the fibrinolytic mechanism. Urokinase has a greater affinity for plasminogen within the formed clot (gel phase plasminogen) than for circulating plasminogen (sol phase plasminogen)[1] and is therefore the most selective thrombolytic agent in current use.[2]**
- **Abbokinase is devoid of antigenic activity in humans – unlike streptokinase. This obviates prior antibody testing and the need for corticosteroids for the prevention and alleviation of allergic response.[3]**
- **Abbokinase is more successful than anticoagulants which do not lyse the clot or reopen the vessel.[4,5]**
- **Abbokinase is more economical and less traumatic than surgery.**

Data sheet information: **Presentation** Abbokinase is available in 10ml vials containing 250,000iu of a highly purified sterile lyophilised formulation of urokinase obtained from cultures of human kidney cells. Urokinase is a plasminogen activator excreted in the urine of normal healthy individuals. When reconstituted with 5.2ml distilled water according to directions, each ml of isotonic solution will contain 50,000iu urokinase, 5mg mannitol and 9mg sodium chloride. **Uses** Abbokinase in vivo and in vitro produces the release of plasmin by an enzymatic action on human plasminogen. Abbokinase has only minimal activity in reducing fibrinogen levels but blood plasminogen levels are reduced, the effect being dose-dependent. Abbokinase is virtually non-antigenic to humans and, in therapeutic doses, is thromboplastin-free. Thrombolytic therapy is indicated in the treatment of vascular occlusions caused by forming or recently formed fibrin clots. Theoretically the best results will be obtained with thrombi less than 24 hours old. Abbokinase is indicated as a thrombolytic agent in pulmonary embolism. **Dosage and Administration** Abbokinase is administered intravenously by continuous infusion, usually for a period of 12 hours. It is recommended that Abbokinase be given in a solution of Normal Saline by constant infusion. An initial loading dose to be given during the first ten minutes of therapy is advocated. This loading dose should be equal to the amount which it is planned to administer over each succeeding period of one hour. Ideally an infusion pump should be used to maintain a constant rate of infusion. Abbokinase is reconstituted with 5.2ml sterile water for injection, without preservatives. For administration the reconstituted solution should be further diluted with normal saline to the total volume of solution (195ml) for a 12 hour treatment including the priming dose. From this solution, 15ml are given over a period of 10 minutes as the priming dose and the remainder over a period of 12 hours at the rate of 15ml/hour. Dosage: It should be noted that patient-to-patient variation in response can be expected, due to individual variation in levels on inhibitory factors. Certain disease states such as uraemia, some malignancies and dyslipidaemias can be associated with an increased plasma level of urokinase or plasmin inhibitors. In other conditions such as massive pulmonary embolism, endogenous fibrinolytic activity may be increased. The recommended dosage regimen for the treatment of pulmonary embolism is: Loading dose: 4,400iu per kg bodyweight over 10 minutes. Constant infusion dose: 4,400iu per kg bodyweight per hour. Duration of infusion: 12 hours. **Contra-indications, Warnings, etc.** Contra-indications: Manifest or recent (i.e. within 3 days) haemorrhage; Any haemorrhagic diathesis. Severe hypertension; During cardiopulmonary resuscitation; During pregnancy or suspected pregnancy. Warnings and Precautions: The major adverse effect of Abbokinase is haemorrhage, usually associated with too high dosage. A high incidence of bleeding from minor skin lesions, therapeutic and diagnostic puncture sites and pre-existing gastro-intestinal lesions has been observed with high dosages. Any evidence of significant internal bleeding necessitates the cessation of thrombolytic therapy. An anti-fibrinolytic agent such as epsilonaminocaproic acid (EACA) may be used as an antidote if required. Epsilonaminocaproic acid should be available for use, if necessary, during infusions with Abbokinase when high doses are being administered. Post-partum for one month. Recent surgery (within 3 days). Concurrent anti-coagulant therapy should be administered cautiously. Mild temperature increases have been observed during thrombolytic therapy with Abbokinase. When there is a history of hypersensitivity to drugs etc., caution is advised and facilities as well as corticosteroids, adrenaline, etc. should be readily available when Abbokinase is infused. Monitoring: The monitoring of fibrinolytic activity and of plasminogen levels is desirable. Pharmaceutical Precautions: The lyophilised powder should be stored at 2-8°C. Reconstituted solution should be used immediately after mixing and secondary dilution. **Legal Category** POM. **Package Quantities** Available in packs of 2 vials of 250,000iu each (List No. 6109). **Further Information** The potency of Abbokinase is expressed in International Units (iu). For practical purposes the iu is considered by most authorities to be equivalent to the CTA unit. The Ploug unit is usually considered to be equal to 1.4iu. **Product Licence Number** 0037/0096. **References** 1. Kakkar V.V, Scully M.F: Thrombolytic therapy. *Brit Med. Rupture of the abdominal oesophagus: a review

P. V. WALSH*

SUMMARY

'Spontaneous' rupture of the oesophagus usually affects the lower third, less commonly the middle third and rarely the cervical oesophagus. Rupture limited to the intra-abdominal oesophagus is rare. Such a case is described here and previously reported cases are reviewed. Vomiting-induced gastro-oesophageal injuries and their aetiology are discussed and the management of spontaneous rupture is reviewed.

Case report

A 58-year-old business executive developed diarrhoea and vomiting the day after returning from abroad. He vomited nine or ten times that evening and experienced epigastric pain. Four hours later the pain suddenly became severe and radiated to the right hypochondrium, and retrosternally. The patient was sweating, dyspnoeic and hypotensive with a bradycardia (60/min).

A diagnosis of myocardial infarction was made by the patient's GP and he was admitted to a medical ward. He was dehydrated, confused and restless with intractable pain, but he was by now normotensive. His lung fields were clinically clear, his abdomen rigid and tender, with a succussion splash.

Investigations showed Hb 17·5 g/dl, WBC 14×10^9/l, normal urea, electrolytes and amylase and a normal ECG. Portable chest X-ray showed a normal mediastinal outline and clear lung fields. Abdominal X-rays did not show free intraperitoneal gas. None the less, a diagnosis was made of a perforated intra-abdominal viscus. Peritoneal lavage yielded a faintly sanguineous fluid, with normal amylase concentration. Ten hours after perforation, laparotomy was performed through a right upper paramedian incision. The only abnormal findings were a haematoma around the cardia of the stomach and into the gastrohepatic omentum, and surgical emphysema along the lesser curve of the stomach. At this juncture, a fibreoptic gastroscope was passed from above, demonstrating a longitudinal mucosal tear on the anterior wall of the oesophagus, just above the oesophagogastric junction. The laparotomy was resumed. The peritoneum was incised at the cardia and a 1-cm vertical perforation of the muscle layer of the oesophagus was found communicating with the lumen. Soiling was negligible. The perforation was closed with interrupted chromic catgut sutures and then covered with a wrap-over of anterior stomach wall. An intubated jejunostomy was fashioned and two wide-bore fenestrated tube drains were placed to the left subphrenic space and along the lesser curve to the cardia. The nasogastric tube was positioned at the antrum. The peritoneal cavity was irrigated with noxythiolin.

Antibiotic treatment was started peroperatively with gentamicin and immediately postoperatively with clindamycin and ampicillin. Artificial ventilation was required to maintain satisfactory blood gases. Culture swabs taken at operation yielded a growth of *Streptococcus viridans*, *Staphylococcus aureus* and *Klebsiella* spp. Ampicillin was discontinued and cloxacillin commenced. On the seventh day bilateral serous pleural effusions were drained (1·8 l from the right, 0·3 l from the left). Gram stain showed no organisms and culture was negative. The effusions did not reaccumulate. Culture swabs taken from the abdominal tube drains on the seventh day yielded a growth of klebsiella sensitive to gentamicin. Tracheostomy was performed on the eighth day. The patient became jaundiced, with a markedly raised direct bilirubin, and his condition deteriorated. Gentamicin was changed to tobramycin and both clindamycin and cloxacillin were stopped on the twelfth day. Leucocytosis and pyrexia suggested intra-abdominal sepsis, so a repeat laparotomy was performed on the fourteenth day. The liver was enlarged, but no hepatic abscess was detected. Collections of pus were found beneath the left lobe of the liver (30–40 ml) and just above the oesophageal hiatus, in the right side of the mediastinum (20 ml). The oesophageal repair was intact and was not disturbed. There was no extrahepatic biliary obstruction and a liver biopsy showed centrilobular congestion with bile thrombi and some liver cell damage. Pus swabs grew *Pseudomonas aeruginosa* and *Klebsiella* spp., both sensitive to gentamicin and tobramycin.

Postoperatively there was a temporary improvement in the patient's condition. Blood cultures were sterile. After consultation with the bacteriologist, tobramycin was changed to amikacin on the twenty-second day Despite intensive support —respiratory, cardiovascular, nutritional (intravenous and enteral) and antibacterial—his condition deteriorated and he died on the twenty-eighth day. Permission for post-mortem examination was refused.

'Spontaneous' injuries of the oesophagus and stomach

The term 'spontaneous' implies injuries produced by vomiting, and excludes those caused by external trauma and instrumentation. It also excludes those cases where there is an obvious mural cause of rupture such as a carcinoma of the oesophagus. Truly spontaneous 'out of the blue' ruptures must be exceedingly rare. The terminology has been debated before, and such alternative names as post-emetic, emetogenic and barogenic have been proposed. 'The deadliest rupture' (Penka et al., 1977) is a graphic but discouraging term, and 'Boerhaave's syndrome' remains a useful heading under which to approach the management of 'spontaneous rupture'. Whether the oesophagus which is normal in every respect can rupture spontaneously, as Barrett (1946) postulated, will not be debated here, but many cases are associated with some abnormality, especially hiatus hernia.

---

* Chester Royal Infirmary, St Martin's Way, Chester.

While rupture is usually induced by vomiting, it can complicate defaecation, epileptic convulsion, parturition, forceful swallowing or laughing (Triggiani and Belsey, 1977).

It is not only the oesophagus that can rupture, however, and Watts (1976) reviewed the literature to find 5 cases of rupture of the stomach caused by vomiting in the absence of other factors such as pyloric stenosis or a mixture of champagne and sodium bicarbonate (Bruno et al., 1963) which cause gastric distension. He found that gastric overdistension commonly produces lesser curvature ruptures, whereas vomiting produces a perforation high on the greater curvature or fundus. He concluded that the vomit-induced rupture occurred while the stomach was in the chest and he attributed the positioning of the rupture to the concurrent presence of a hiatus hernia. He also observed that the mucosal laceration of the Mallory–Weiss syndrome was commonly found in the stomach when a hiatus hernia was present, and in the oesophagus when there was no hernia. Stilwell (1978) recently reported a further case of intrathoracic rupture of a hiatus hernia in a 70-year-old woman who was admitted with a strangulated femoral hernia.

The mucosal laceration of the Mallory–Weiss syndrome can, as stated, occur in the stomach or in the oesophagus. Usually, the haemorrhage is self-limiting, but blood loss may be heavy, and 5 of the 21 cases originally described by Mallory and Weiss bled to death. Sometimes the bleeding point may be accessible through a gastrotomy but clearly it will not be so easily exposed if it is in the oesophagus. Atkinson and his colleagues (1961) reported 11 patients with mucosal tears at the oesophagogastric junction. Only 5 of these were cases of typical Mallory–Weiss syndrome, and there was one case of truly spontaneous tear, and one case each of tear induced by epilepsy, asthma and coughing. The tears were longitudinal, up to 3·5 cm long and 1·4 cm wide, frequently multiple and situated above, below, or across the cardia, anterior or posterior. It has been stated (Holmes, 1966) that Mallory–Weiss syndrome and Boerhaave's syndrome are not different forms of the same condition since there are anatomical, pathological and clinical differences between the two lesions. Zikria et al. (1965), however, described a case of Mallory–Weiss syndrome who continued vomiting after admission and developed a perforation of the oesophagus. Van de Velde and his colleagues (1976) and Bruno and his colleagues (1963) have reported cases of full-thickness rupture with coexistent separate mucosal tear. The attachment of a label of 'Mallory–Weiss syndrome' should not lull the clinician into complacency about the management of a case of haematemesis. Furthermore, haematemesis from duodenal ulcer (Zikria et al., 1965; Callaghan, 1972) and oesophageal varices (van de Velde et al., 1976) have been complicated by oesophageal perforation.

Interstitial haemorrhage in the lower oesophagus caused by vomiting with the production of a submucosal haematoma has been described, under the heading 'oesophageal apoplexy' (Smith et al., 1974). Of the three elderly ladies described (aged 60, 61 and 66) two had a sliding hiatus hernia and the third gave a long history of dyspepsia and heartburn. All developed the haematoma on the posterior wall of the lower oesophagus and presented with pain and dysphagia. All recovered fully on conservative management.

Kelley et al. (1972) described an intramural perforation in a 21-year-old man who developed dysphagia as he was recovering from a respiratory tract infection with coughing and sneezing. He vomited 10 ml of blood and then experienced substernal pain. Barium swallow showed narrowing of the lumen of the mid-oesophagus with some extraluminal barium. Oesophagoscopy showed a 15-mm tear in the mucosa of the mid-oesophagus on the posterior wall. He was treated conservatively until, after 2 weeks, his dysphagia worsened. Repeat endoscopy revealed the tear as before, with a 4-cm submucosal track leading from it. In view of the danger of perforation developing, right thoracotomy was performed but there was no apparent external abnormality of the oesophagus. It is possible that this patient developed a haematoma, as a result of coughing and sneezing, and that this caused his dysphagia. Rupture of the haematoma into the lumen would cause him to 'vomit' the 10 ml of blood described, leaving a haematoma cavity, rather like the ones described by Smith and his colleagues (1974), though a few centimetres higher in the oesophagus.

The conditions outlined so far form an interesting spectrum of injuries.

Boerhaave's syndrome—full-thickness rupture of the oesophagus—may occur at any level. The laceration is nearly always vertical but may rarely be transverse, as in the first reported case, that of the unfortunate Baron de Wassanaer, whose oesophagus disrupted completely. There may rarely be multiple perforations (Van de Velde et al., 1976). The perforation may measure anything up to 10 cm long but is usually of the order of 6 cm in length. It is most common in the lower third, just above the diaphragm, 80–90 per cent being on the left side, and perforation into the left pleural cavity has usually taken place by the time of admission. Rupture in the middle third is more commonly on the right side (6 out of the 9 cases reviewed by Holt et al., 1978). Most series show a male preponderance. Barrett (1946) quoted Walker's 1914 series of 22, all but 2 of whom were male. Mori et al. (1977) found 59 cases in the Japanese literature over a 40-year period and 53 were male. All of the 8 late-diagnosed cases reported by Harrison et al. (1976) were male. Keighley et al. (1972) reported 9 males out of 12 cases over a 20-year period. Triggiani and Belsey (1977), however, found no male preponderance in their 11 cases over a 25-year period. The victim is usually in his fifth or sixth decade, but cases have occurred in infancy, childhood and adolescence.

Rupture not uncommonly occurs in association with a hiatus hernia or below a stricture, though it has been described (Harma et al., 1968) occurring above a stricture. The literature contains many assertions of an association with oesophagitis and there has been one case reported (Habein, 1977) in a 37-year-old man with Ehlers–Danlos syndrome and a small sliding hiatus hernia. There is an increased incidence among chronic alcoholics. Penka et al. (1977) described 5 cases of idiopathic muscular hypertrophy of the oesophagus, 2 of whom suffered spontaneous rupture. The patient presented here had previously complained of mild dysphagia, and, although the oesophagus was endoscopically normal, it is possible that this was an example of mild dysfunction. Perhaps more cases have an unrecognized abnormality of function or structure than are detected.

The pressure required to rupture the cadaveric oesophagus *in situ* has been measured (Tidman and John, 1967) and a mean figure of 4·6 lb/in^2 produced a tear averaging 2·7 cm in length. Twelve of the fifteen tears were on the left of the lower third, just above the diaphragm, while the remaining three were on the right just below the azygos vein. The authors concluded that the upper end of the oesophagus must be occluded to permit such a pressure to be achieved.

The usual explanation for the site of rupture is that the oesophageal wall is unsupported on the left in the lower third and on the right in the middle third. Edwards (1969) observed that during barium examinations under fluoroscopy, patients who demonstrated a small hiatus hernia on the antigravity film also produced a hernia when they retched. This observation suggests that under conditions of sudden forceful vomiting, such patients would herniate the stomach into the chest and perhaps create a redundant 'loop' of oesophagus in the lower mediastinum. Patients with an overt sliding hiatus hernia presumably herniate maximally during the increased intra-abdominal pressure of vomiting to produce a redundant loop. If this 'loop' kinks, it would occlude the lumen and provide the closed viscus that Tidman and John (1967) imply is necessary for rupture to occur. If kinking occurs low in the oesophagus, the lower third will rupture. If the kink occurs around the azygos vein, the middle third will rupture, the rupture in each case occurring on the convex side of the loop —left in the lower third, right in the mid-third.

Spontaneous rupture of the cervical oesophagus is rare. Russell and MacDonald (1968) reviewed the condition when the first case, reported by Russell in 1953, presented again after 26 years with a further very small perforation in the cervical oesophagus. The patient gave a long history of mild dysphagia for solids and, on endoscopy, the cricopharyngeus was noted to be tight. The authors found one other reported case, also with a minute perforation, which was treated conservatively. Mori et al. (1977) found only 2 reported cases of spontaneous upper oesophageal rupture in their review of the Japanese literature over 40 years.

Intra-abdominal 'spontaneous' perforation of the oesophagus

There are very few recorded cases of spontaneous rupture limited to the intra-abdominal portion of the oesophagus and without involvement of, and extension into, the pleural spaces.

The first recorded, and often quoted, case was an intraperitoneal perforation in a woman in her early twenties (Sencert, 1911). She had several months' history of postprandial abdominal pain relieved by vomiting. Suddenly, one afternoon, while she was sitting reading, her oesophagus perforated. At laparotomy she was found to have generalized peritonitis and a perforation 'the size of a 50 centime piece' in the oesophagus, 2 cm above the cardia. Macroscopically, this was a chronic ulcer, and it was repaired using a wrap-over of gastric fundus. The patient survived. This was an unusual condition, but the rupture was not spontaneous.

Thornley and Wallwork (1978) reported an apparently vomiting-induced intraperitoneal perforation in a 30-year-old woman. The condition was remarkably benign and 4 weeks elapsed before the patient sought attention for her left-sided chest and shoulder pain. Laparotomy showed a 2-mm perforation in the anterior wall of the oesophagus near the cardia. The patient survived. The case appears to be unique.

Triggiani and Belsey (1977) had 1 case of intra-abdominal rupture in their series of 11 cases over 25 years. It is presumably the same case that had a pneumoperitoneum, implying intraperitoneal rupture, but no further account is given of the case, and no indication is given as to whether the rupture in this case was entirely intra-abdominal.

Bruno and his colleagues (1963) reported a case of rupture extending for 5 cm in the posterior wall of the oesophagus and extending for 1·5 cm into the posterior wall of the stomach. The patient had mediastinitis, gas under both diaphragms on X-ray and subcutaneous emphysema in the right supraclavicular fossa. At laparotomy 'there was no evident perforation into the peritoneal cavity', and gastrotomy merely showed blood 'oozing from the mucosa of the entire stomach'. It is not clear whether the subdiaphragmatic gas was intra- or extraperitoneal. Subdiaphragmatic gas is unusual but the literature contains several reported cases of oesophageal rupture extending into the stomach. Air could enter the peritoneal cavity if an oesophageal rupture extended into the peritonealized surface of the stomach or oesophagus.

Strauch and Lynch (1965) reported the first recorded case of spontaneous, subphrenic, extrathoracic rupture of the oesophagus. Their patient, a 53-year-old man, had a relatively benign presentation, and on the third hospital day a contrast swallow X-ray was performed, showing a subphrenic leak. At laparotomy an extraperitoneal abscess was found in relation to a left posterior oesophageal perforation. Simple drainage was carried out. A left subphrenic abscess developed and was drained. The oesophagocutaneous fistula which developed closed spontaneously. The patient had been shown to have a small sliding hiatus hernia and a scarred duodenal bulb more than a year earlier, and had previously also complained of mild dysphagia. The authors attributed the rupture to cardiospasm causing hold-up during swallowing, yet an oesophagocutaneous fistula would be unlikely to close spontaneously if it were proximal to an obstruction.

The case presented here was similar to that of Strauch and Lynch: both were subphrenic and extraperitoneal, but while their case was of benign presentation, without mediastinitis, the present case was very ill from the outset.

As to the aetiology of the present case, the rupture was caused by vomiting and some agency was necessary to occlude the oesophagus above the site of rupture. It is suggested that the oesophagus was occluded by the diaphragm, which contracted inappropriately but forcefully at the moment of emesis. The glottis closes during vomiting, and the diaphragm certainly becomes 'fixed' as a result. There was no other possible anvil upon which the advancing hammer of vomit could strike the oesophagus.

Discussion

Presentation

Most cases of Boerhaave's syndrome present within a few hours of perforation, although some cases present days later. Many, despite presenting early, are not diagnosed for some days. The impressive clinical feature is the sudden severe pain, not responding to powerful analgesics, and situated in the retrosternal and epigastric regions. It may also radiate to the hypochondria, the renal areas, the shoulders, or the middle of the back. The patient is usually profoundly ill, suggesting myocardial infarction, perforated peptic ulcer, pancreatitis or dissecting aortic aneurysm. The upper abdomen is usually tender and rigid. The most important diagnostic sign is surgical emphysema palpable at the sternal notch and, rarely, even extending up into the face (Russell and MacDonald, 1968). This sign, however, also occurs in lacerations or rupture of the trachea or main bronchi, and for this the treatment is quite different. While surgical emphysema is usually present early, especially in the higher perforations, several cases have been reported where this sign was long delayed or completely absent. It was found in only 7 of the 12 cases reported by Keighley and his colleagues (1972).

In most cases examination of the lung fields reveals the signs of an effusion or hydropneumothorax. Aspiration of the effusion may show an acid pH or frank gastric contents. Initially it may be sterile and serous, but bacteria nearly always appear later. The amylase concentration may be raised due to swallowed saliva in the effusion. The 'tetrad of Goth' attached to Boerhaave's syndrome comprises prostration, respiratory distress, chest pain and crepitus in the sternal notch. Hamman's sign, a 'mediastinal crunch' audible in the precordium, may be elicited.

Investigations

Investigations usually show normal haemoglobin concentration, a neutrophil leucocytosis, normal plasma urea and electrolytes and normal amylase, although Boerhaave's syndrome has been reported as a complication of pancreatitis. The cardiograph is normal in most cases.

Plain X-rays of the chest and abdomen may show an effusion, commonly on the left side, and mediastinal widening. Differentiation from thoracic aortic dissection or aneurysm leakage may be difficult, but the vertical lines of mediastinal emphysema will seal the diagnosis (excepting tracheal or bronchial perforation). Spontaneous pneumomediastinum and pneumopericardium have also been described in anorexia nervosa but the presentation is benign compared with oesophageal rupture (Donley and Kemple, 1978). In order to demonstrate emphysema, however, the X-rays have to be of good quality and adequate penetration, so that 'portable' X-rays of a restless, semi-recumbent patient are rarely helpful. Under ideal viewing conditions, later examination of the chest X-ray of the case reported here showed faint lines of mediastinal emphysema but these were not observed at the time of admission. Both posteroanterior and lateral views should be obtained. When the topic was reviewed by Toghill et al. in 1968, air had never been shown below the diaphragms, but this has now been reported by Bruno et al. (1963), Keighley et al. (1972) and Thornley and Wallwork (1978). Pneumopericardium was reported by Mansour and Teaford (1973) but the case they described had previously undergone oesophagogastrectomy for a benign stricture of the lower oesophagus and subsequent fundic patch oesophagoplasty for recurrent stricture, 14 months before final presentation with oesophageal rupture into the pericardium.

The V-sign of Naclerio is the outlining by extrapleural gas of the mediastinal and diaphragmatic pleurae (posteroanterior view).

To confirm the diagnosis and locate precisely the site of the rupture, a contrast swallow is undertaken. Gastrografin passes too quickly and leaked barium causes a severe tissue reaction; iodized oil (10–20 ml) is recommended (Triggiani and Belsey, 1977). The patient may be too ill to cooperate, however, and a small supradiaphragmatic collection may be mistaken for a paraoesophageal hiatus hernia. In 1946, Barrett stated that there was a place for oesophagoscopy, and although various authors have regarded it as unrewarding or dangerous, there is no doubt that the modern flexible fibreoptic instrument will diagnose and locate perforation more surely than any other measure short of surgical exploration.

Furthermore, precipitating or associated diseases such as oesophageal varices, duodenal ulcer or hiatus hernia will be detected and, more important, oesophageal lesions such as carcinoma, stricture or impacted foreign body or food will be obvious when they could otherwise remain undetected. In one case when there was no surgeon available who was sufficiently experienced to perform thoracotomy, the perforation seen on endoscopy was intubated endoscopically to drain the mediastinum and instil antibiotics. The patient developed an empyema and oesophagocutaneous fistula requiring exploration, but he survived (Harma et al., 1968). This case also had a mild chronic stricture *below* the perforation.

Treatment

With the exception of cervical oesophageal perforations, which may usually be treated conservatively (Triggiani and Belsey, 1977), once oesophageal rupture has been diagnosed, formal surgical exploration is mandatory. The survival rate varies inversely with the time elapsed from perforation to operation. While there have been reports of spontaneous recovery on conservative measures (Sanderson, 1965; Hammerschmidt et al., 1973), these are unusual rather than trend-setting.

There are differences between vomiting-induced and instrumental perforations of the oesophagus. The high pressure injection of septic vomit into the mediastinal tissue planes causes a severe reaction which is graphically described in the published literature on the subject. The description is of a blackened, bulging mediastinal pleura disgorging an offensive mixture of blood and vomit, with much devitalized tissue. An instrumental perforation is by comparison a relatively sterile and gentle process. The longer delay before diagnosis in Boerhaave's syndrome compounds the morbidity and mortality, especially when the patient uses this time to slake his thirst, as he often does. Thus, mortality is much greater, taken overall, in Boerhaave's syndrome than in instrumental perforation.

As soon as the diagnosis is suspected, broad spectrum antibiotic treatment should be commenced. Thoracotomy on the appropriate side provides adequate access in most cases, but in a low perforation extending below the diaphragm a left thoracoabdominal approach has advantages (Craddock, 1968). For subphrenic extraperitoneal perforations without extension of the rupture above the diaphragm, however, a purely abdominal approach cannot be recommended. In the case reported here the surgery performed was not excessively delayed and achieved a sound repair of the perforation. The antibacterial measures taken were both prompt and thorough. The bacteria isolated are presumed to have been the cause of the suppuration, but despite carefully monitored levels of appropriate antibiotics, sepsis was uncontrolled and appears to have been the cause of death. Blood cultures and culture of the central venous catheter tip were all sterile, as were the pleural effusions, which is most unusual.

Peritoneum and pleura cope well with, and contain, sepsis as a rule whereas mediastinitis is lethal. Gas permeates through the mediastinal tissues following oesophageal rupture and presumably bacteria accompany the gas. The extensive fasciotomy and drainage provided by the more usual transthoracic approach may be essential to the management of mediastinal cellulitis, and possibly more important than systemic antibiotic therapy. Thoracotomy is therefore indicated even in low ruptures.

It may be that oesophageal rupture with perforation into a pleural cavity carries a better prognosis than when the infective process is confined to the mediastinum, on purely pathological grounds. This would be difficult to prove, however, since the early appearance of a pleural effusion leads to earlier diagnosis and treatment than in the more occult cases.

The overall mortality remains high, but prompt treatment in specialized units produces excellent results. Triggiani and Belsey (1977) reported 1 death out of 11 cases over 25 years. Five of these cases were diagnosed 24 h or more after perforation, yet 4 survived. The survival of the late-presenting cases, however, demands drastic measures which may be outside the usual repertoire of the general surgeon. The primary, life-saving measure is not beyond him, however, and the secondary reconstruction may be contemplated at leisure.

The early case with little contamination should be débrided and then meticulously repaired in layers. The visible muscle split is usually shorter than the mucosal tear. Keighley and his colleagues showed that the muscle split was 2 cm shorter in the 7 cases in whom accurate measurements were taken (Keighley et al., 1972). Others have made the same observation. The muscle split must therefore be extended before the mucosa is sutured. Interrupted sutures are used, with catgut, silk and stainless-steel wire all having their advocates. Stainless-steel wire, however, causes the least reaction in already inflamed tissue.

If there is an extensive defect in the oesophagus following débridement, it is possible to use adjacent tissues to make good the defect. Thal and Hatafuku (1964) described the successful use of an intact fold of gastric fundus mobilized above the diaphragm and sutured to the edges of the defect. Millard (1971) used a pericardial flap to repair a defect resulting from necrosis of a previously repaired rupture.

Hatcher (1973) described his experience with the use of a T tube to intubate the oesophagus at the site of rupture, both traumatic and spontaneous. While this method necessarily establishes an oesophago-cutaneous fistula, this closes spontaneously in a high proportion of cases. Harrison et al. (1976) reported 5 survivors in 7 cases who presented late (average 57 h after perforation) using this method. A wide-bore tube is used.

Mayer et al. (1977) reported 5 cases of oesophageal perforation—3 spontaneous—with delayed recognition. Their experience underlines the need for prompt surgery and ruthless débridement of dubious tissue without primary regard for oesophageal continuity.

In the series of Triggiani and Belsey (1977), 2 patients were treated with pleural drainage and jejunostomy feeding only. One died of sepsis while the other developed a chronic empyema. Primary suture was carried out in 4, but in 5 resection was necessary. One case underwent oesophagogastrostomy, but 4 cases needed oesophagectomy with cervical oesophagostomy and gastrostomy. Colonic interposition at a later stage restored continuity.

Conclusion

As other authors have speculated, this condition is probably more common than is realized. Massive myocardial infarction, thoracic aortic dissection, overwhelming pneumonia, exsanguination from varices, duodenal ulcer or multiple gastric erosions and severe pancreatitis are just a few of the diagnoses which may be written on the death certificate of the patient who has been admitted profoundly ill and died rapidly. For the clinician to be aware of the condition is the first step towards refuting its evil reputation.

Dysphagia following selective vagotomy

S. I. SULEIMAN, S. A. MAGLAD AND M. HOBSLEY*

SUMMARY

Progression of dysphagia after vagotomy to the stage of complete obstruction due to a peri-oesophageal fibrotic collar needing operation is a rare event. Review of the 4 such cases previously described, all needing further operation and all after truncal vagotomy, indicates that the oesophageal mucosa was normal on oesophagoscopy and that bouginage appeared to make the condition worse. This paper describes the first patient in whom (*a*) *the vagotomy was selective and* (*b*) *no bouginage was carried out before the condition was relieved by a further surgical operation.*

In this paper we describe a very rare cause of dysphagia following vagotomy and indicate how to diagnose and treat the condition.

Case report

A 58-year-old male Sudanese, with a 15-year history typical of duodenal ulcer pain, had recently started vomiting. The barium meal showed a deformed duodenal cap with pyloric outlet obstruction.

On 24 March 1976 he underwent selective vagotomy (Tanner, 1966) with a Heineke–Miculicz pyloroplasty. He made an uneventful recovery, started eating solid food on the fifth day and was allowed home on the tenth day on a full diet.

On 14 April the patient was readmitted complaining of dysphagia with a mild retrosternal pain and regurgitation. The dysphagia had commenced a week after discharge from hospital, i.e. 2 weeks after the operation. At first there had been difficulty only with solids, but within 3 days the dysphagia had progressed to complete inability to swallow.

Intravenous fluid therapy was started. When a barium swallow was performed the contrast medium reached the lower oesophagus and was regurgitated. Fibre-endoscope oesophagoscopy showed a normal mucosa but the lumen of the lower oesophagus was irregular and narrowed and would not yield to the 7-mm fibre endoscope. After 48 h a thin Gastrografin swallow showed a narrowed lower oesophagus and there was a trickle of contrast medium into the stomach (*Fig*. 1).

On 18 April the patient was re-explored. The lower oesophagus, denuded at the previous operation, was found to be surrounded by tough fibrous tissue, particularly anteriorly and laterally. The fibrous tissue was easily dissected from the oesophageal muscle but was firmly adherent to the peri-oesophageal tissue. The fibrotic collar was removed and both silk sutures previously used for ligating the vagal trunks were found amidst the tough tissues. The patient's postoperative recovery was uneventful and he could swallow solid food within a week. At follow-up, 18 months later, the patient remained symptom-free.

Discussion

Many believe that vagotomy denervates the lower oesophageal sphincter mechanism and leads to loss of peristalsis and a form of achalasia (Moses, 1947; Harris and Miller, 1960). However, Edwards (1970) showed by radiology and manometry in patients with post-vagotomy dysphagia that the lower oesophageal sphincter was intact and that peristalsis occurred normally. Denervation of the lower oesophagus in dogs is only achieved by vagal section high in the hila of the lungs (Carveth et al., 1962); this may be why the incidence of dysphagia is higher after transthoracic vagotomy (Grimson et al., 1947) than after abdominal vagotomy (Wirthlin and Malt 1972).

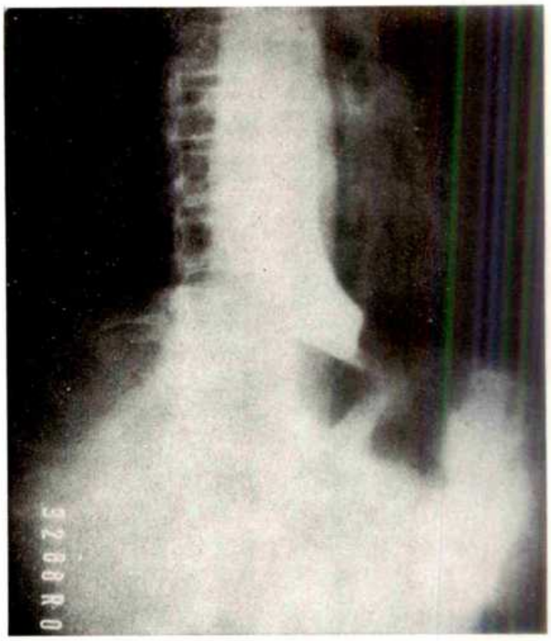

Fig. 1. Gastrografin swallow showing narrowing of the lower oesophagus which proved to be due to peri-oesophageal fibrosis.

Post-vagotomy dysphagia can certainly be caused by oesophagitis due to reflux, with or without a hiatus hernia (Beal, 1948; Clarke et al., 1965; Johnson, 1965). Reflux oesophagitis can be diagnosed by oesophagoscopy.

The literature (Bruce and Small, 1959; Guillory and Clagget, 1967; Postlethwaite et al., 1969; Spencer, 1975) also describes 4 patients after truncal vagotomy in whom operation was needed to relieve complete oesophageal obstruction due to pressure from a fibrous collar. In all cases the dysphagia started 2–3 weeks following the vagotomy, oesophagoscopy—when performed—showed a normal mucosa and dilatation of the oesophagus was ineffectual. It is particularly interesting to note the comment of Postlethwaite et al. (1969) that 'for 2 months repeated dilatations were performed but the size of the oesophageal lumen gradually decreased'.

Our patient is the first in whom this rare form of dysphagia occurred after selective vagotomy. Presumably the condition can also arise after proximal gastric vagotomy, as in all forms of vagotomy the lower oesophagus is denuded. The differentiation of

this rare complication from dysphagia due to oesophagitis depends on the characteristically short time interval between the operation and the onset of symptoms (7–21 days), the relentless progression to complete, or nearly complete, inability to swallow and the finding on endoscopy of normal mucosa at the lower end of the oesophagus. The evidence of the previously described 4 cases suggests that bouginage is ineffective, because the rigid fibrotic collar cannot be stretched, and repeated attempts at bouginage cleary carry a risk of perforation of the oesophagus. We therefore suggest that the correct management should be early laparotomy and excision of the fibrous mass, without preliminary abortive attempts at oesophagoscopic dilatation. We successfully adopted this policy in the management of our patient.

Anastomotic recurrence in the oesophagus complicating gastrectomy for adenocarcinoma of the stomach

D. N. PAPACHRISTOU, M. KARAS AND J. G. FORTNER*

SUMMARY

Gastric adenocarcinomas often spread to the distal oesophagus. Failure to control the disease in this area during total and proximal subtotal gastrectomy results in recurrence at the oesophageal anastomosis. The incidence of recurrence in a series of 351 such patients was 10 per cent and was influenced by the location of the main lesion, the stage of the disease, the presence of tumour at the margin of resection and the length of clearance of the oesophageal margin. Recurrences were prevented only with in vivo *margins greater than 12 cm. Dysphagia combined with radiological signs of oesophageal obstruction was diagnostic of anastomotic recurrence regardless of the results obtained by oesophagoscopy and biopsy.*

Treatment was seldom effective in patients developing recurrence. Complete excision of the entire recurrent process offered the only hope for a long survival in these patients. Prevention by obtaining adequate oesophageal clearance at the time of gastrectomy is the only reasonable approach to this problem. The adequacy of resection cannot be judged accurately by intraoperative palpation of the oesophagus or by frozen section examination of the surgical margins.

OESOPHAGEAL invasion is common in patients undergoing proximal subtotal or total gastrectomy for primary gastric adenocarcinoma, the incidence depending on the location of the main lesion in relation to the gastro-oesophageal junction. Thus, 30–90 per cent of all resectable adenocarcinomas of the cardia (Pack, 1949; Morson, 1961; Paulino and Roselli, 1973) and 25 per cent of corpus primaries (Paulino and Roselli, 1973) invade the distal oesophagus either directly or by embolization of intramural and peri-oesophageal lymphatics (Morson, 1961). Failure to eradicate the entire invading process in the oesophagus of such patients may predispose to neoplastic recurrence at the oesophageal anastomosis following resection.

Theoretically, recurrence of a resected gastric neoplasm at the oesophageal anastomosis may be due to, first, neoplastic remnants left behind at the margin of resection following transection of the oesophagus through an area invaded by disease (Morson, 1961; Miller, 1962; Paulino and Roselli, 1973); incomplete resections of this type are reportedly encountered in 20–44 per cent of all gastric cancer patients undergoing total or proximal subtotal gastrectomy (Morson, 1961; Zinninger and Collins, 1965; Paulino and Roselli, 1973). The second cause may be skip submucosal lesions located above the line of oesophageal transection. These lesions are caused by intramural permeation of the disease (Morson, 1961) and can be easily missed intraoperatively. The third cause may be infiltration of the peri-oesophageal tissues in the posterior mediastinum; according to Payne and Bernatz (1976) disease in the mediastinum is more often responsible for these recurrences than failure to obtain tumour-free oesophageal margins.

Table I: INCIDENCE OF ANASTOMOTIC RECURRENCE IN THE OESOPHAGUS ACCORDING TO STAGE AND LOCATION OF THE GASTRIC TUMOUR

Location	Stage I and II	Stage III and IV	Total
Cardia	11/30 (36%)	14/54 (26%)	25/84 (28%)
Corpus	3/45 (6%)	7/148 (5%)	10/193 (5%)
Total	14/75 (18%)	21/202 (10%)	35/278 (12%)

Recurrence of a gastric neoplasm at the oesophageal anastomosis is a grave complication which reduces the survival rate (Boyd et al., 1958; Miller, 1962; Humphrey and Kerstens, 1976) and re-establishes dysphagia. The present report is the first on this subject and examines the incidence, predisposing factors, clinical features, management and consequences of oesophageal anastomotic recurrence in 35 gastric cancer patients treated with total and proximal subtotal gastrectomy.

Patients and methods

The study involves 351 patients with primary adenocarcinoma of the gastric cardia ($n = 100$) and corpus ($n = 260$) treated with total ($n = 260$) or proximal subtotal ($n = 91$) gastrectomy between 1950 and 1975 at Memorial Sloan-Kettering Cancer Center. Oesophagoscopic and upper gastrointestinal X-ray studies preceded all operative procedures. The adequacy of oesophageal resection during gastrectomy was determined by palpation of the oesophagus. Frozen section examination of the surgical margins was carried out in 130 patients. Resected neoplasms were classified according to the TNM system (American Joint Commission for Cancer Staging and End Results Reporting, 1971). Specimen dimensions were obtained from available pathology reports. The macroscopic margin of an oesophageal specimen was defined as the distance between the palpable periphery of the main lesion and the line of oesophageal transection. The microscopic margin was the distance between the microscopic border of the main lesion and the same line. These measurements were carried out in fresh specimens and they must be doubled in order to correspond to *in vivo* dimensions (Miller, 1962; Rosi, 1969). Patients developing anastomotic recurrence were readmitted to the same hospital where histological confirmation of the diagnosis was always obtained.

Results

Incidence

The overall incidence of anastomotic recurrence in the present series was 10 per cent (35/351); among patients who survived their operation and became liable to recurrence the incidence was 12 per cent (*Table I*). The incidence was markedly influenced by the location of the primary tumour and the TNM stage (*Table I*). Thus, recurrences appeared in 28 per cent of patients with neoplasms of the gastric cardia as compared with only 5 per cent of those who had primaries of the corpus ($P < 0.001$, χ^2 test). Patients

Table II: INCIDENCE OF ANASTOMOTIC RECURRENCE IN THE OESOPHAGUS ACCORDING TO SIZE OF OESOPHAGEAL MARGINS

Macroscopic margin*	Survivors	Recurrence rate
0 cm	16	2 (12%)
1 mm–2 cm	61	10 (16%)
2·1 cm–4 cm	134	18 (13%)
4·1 cm–6 cm	50	5 (10%)
>6 cm	17	0 (0%)
Total	278	35/278 (12%)

* Specimen dimensions.

with early stage disease seemed more prone to anastomotic recurrence than patients with advanced stage disease regardless of tumour location (*Table I*). Thus, the incidence of recurrence was 18 per cent following treatment of TNM stage I and II disease as compared with 10 per cent following treatment of stage III and IV lesions, but the difference was not statistically significant ($P<0·1$).

Oesophageal margins

Transection of the oesophagus close to the tumour predisposed to recurrence at the oesophageal anastomosis. This was indicated by two facts: (*a*) the median length of the macroscopic oesophageal margins in patients who eventually developed recurrence was only 1·5 cm (range 0–6 cm) as compared with 2·9 cm (0–9 cm) in patients remaining free from anastomotic recurrence ($P<0·05$, rank sum test); (*b*) the incidence of anastomotic recurrence declined as the median length of the macroscopic oesophageal margins increased (*Table II*). Recurrences were not encountered among 17 patients whose oesophageal margins were 6 cm or more in length. The low incidence of recurrence among patients in whom the oesophagus was divided at the edge of the tumour (*Table II*) is explained by the fact that these patients were treated for palliation and only a few of them survived long enough to develop local recurrence.

In 20 per cent of the patients (73/381) the line of oesophageal transection was found to be invaded by tumour, i.e. the length of the microscopic margin was zero. The incidence of recurrence in these patients was 16 per cent (12/73); it increased, however, to 23 per cent when calculations included only patients who survived their operations (12/53). The same incidence in patients with histologically free oesophageal margins was 10 per cent (23/227). The difference was statistically significant ($P<0·001$, χ^2 test). Thus, histologically positive oesophageal margins were responsible for only 34 per cent of all anastomotic recurrences (12/35), the remainder being caused by other factors. Histologically positive margins were not contributory to the high incidence of anastomotic recurrence observed in patients with tumours of the gastric cardia because they were only encountered in 36 per cent of them as compared with 40 per cent of patients operated upon for tumours arising in the corpus of the stomach.

Extent of oesophageal invasion

Recurrences were mainly associated with neoplasms arising high in the stomach and involving segments of oesophagus. The median length of oesophagus macroscopically occupied by tumour was only 0·8 cm (range 0–2·2 cm) in patients who remained free from recurrence as compared with 2·3 cm (range 1·5–5 cm) in those who developed anastomotic recurrence ($P<0·05$, rank sum test). Microscopic spread of the neoplasm beyond its palpable edge was present in most of the specimens and was either continuous with the primary or discontinuous, forming skip submucosal foci proximal to it. Invasion in continuity with the main neoplasm was confined within a maximum radius of 4 cm from its macroscopic border, while discontinuous spread was confined within a 6 cm radius. Two patients were exceptional in this regard because they had involvement of the entire oesophagus extending all the way to the thoracic outlet. Both these patients died following re-exploration undertaken for the eradication of all disease from the oesophagus.

Frozen section examination of the oesophageal margin before construction of the anastomosis was carried out in 130 patients. Ten of them subsequently developed recurrence at the anastomosis despite the fact that their margins were clear histologically (7·6 per cent incidence). The incidence of anastomotic recurrence among patients operated upon without the use of frozen section examination was 11 per cent (25/221). The difference between the two groups was not statistically significant.

Clinical manifestations

Dysphagia was present in all patients who had recurrence at the anastomosis. Dysphagia was persistent and progressive. Patients postponed medical consultations for an average of 38 days, attributing their symptoms to a variety of 'benign' causes such as 'ulcer', 'dyspepsia' etc. Additional delay in treatment was occasionally caused by the physicians, who insisted on obtaining histological proof of recurrence before initiating therapy. Thus, 5 patients were subjected to multiple oesophagoscopic examinations because oesophageal biopsies were negative. When finally diagnosis was confirmed histologically, none of these patients was in a position to undergo effective treatment. False negative oesophageal biopsies were common in the present series and were caused by sampling of normal oesophageal mucosa overlying the recurrent process.

Recurrences were best diagnosed by a barium swallow examination (*Fig.* 1). Radiological signs of oesophageal obstruction at the site of the anastomosis combined with a history of persistent dysphagia were virtually diagnostic of anastomotic recurrence. This combination was present in all 35 patients. There was only one patient in the entire series who presented with such a combination and yet he was found to have oesophageal obstruction caused by a band of adhesions. Dysphagia was relieved following re-exploration and division of the constricting band in this patient.

Management

Patients developing anastomotic recurrence were best treated with re-exploration and resection of the recurrent process. Resections were effective only when they did not leave tumour in the mediastinum and oesophagus. This was accomplished in only 4 patients out of 12 re-explored. Two of the 4 are still alive 2½ and 3½ years later; the remaining 2 died postoperatively from surgical complications. Incomplete resections were carried out in 4 patients all of whom died within 3 months from second recurrence in the chest and/or generalized metastases. Nine patients were managed with radiation therapy; 5 succumbed during treatment and 4 experienced transient palliation. None of them lived more than 5 months. Oesophageal dilatations were carried out in 3 patients who subsequently received radiation therapy and 2 other patients were managed with intubation of the oesophagus. The longest survivor in this group was a patient whose oesophageal tube continued to function for 6 months until he died from distant metastases. All other patients succumbed within 4 months. Finally, 3 patients were managed with a feeding gastrostomy; 1 survived the procedure with palliation for 3 months, the other 2 died from surgical complications or from aspiration.

Prognosis

Anastomotic recurrence had a profound impact: the median survival after the onset of dysphagia was only 5 months and only 2 out of 35 patients developing recurrence lived beyond the third postoperative year. These two individuals were the only long term survivors out of 14 patients with stage I and II lesions who developed recurrence. These results should be compared with a 55 per cent 5-year actuarial survival of stage I and II patients who did not develop anastomotic recurrence. The difference in survival between stage III and IV patients with and without recurrence was less striking. Thus, there were no 2-year survivors among stage III and IV patients developing recurrence at the anastomosis, while the 2-year actuarial survival of their counterparts who did not develop recurrence was 21 per cent. Most importantly, those who did not develop recurrence died under much better circumstances than patients with recurrence.

Discussion

Recurrence of a gastric neoplasm at the oesophageal anastomosis is due to inadequate local control of the disease in the oesophagus and the posterior mediastinum (Payne and Bernatz, 1976) and appears to be a common late postoperative complication of total and proximal subtotal gastrectomy (Miller, 1962). Its incidence mainly depends on the location of the primary neoplasm in relation to the oesophagus (Miller, 1962), the adequacy of oesophageal resection (Miller, 1962; Humphrey and Kerstens, 1976; Payne and Bernatz, 1976) and, as this study showed, on the stage of the disease at the time of surgery. Its real incidence must be higher than that reported because it is unknown how many patients who die from metastases have oesophageal recurrence but not dysphagia. Indeed, autopsies performed in patients dying 6–37 months after proximal subtotal gastrectomy for adenocarcinoma of the cardia revealed recurrence at the anastomosis in 55 per cent according to one report (Humphrey and Kerstens, 1976).

Of all gastric neoplasms in this series, those arising in the cardia were the most prone to anastomotic recurrence (*Table I*). Miller (1962) reported a similar incidence in his series. Adenocarcinomas of the cardia reportedly demonstrate the same ability to cause widespread intramural invasion of the oesophagus as squamous oesophageal primary carcinomas (Humphrey and Kerstens, 1976) and they are far more dangerous in this regard than lesions arising in the gastric corpus (Paulino and Roselli, 1973). In a histological study conducted in patients with resectable adenocarcinomas of the cardia Morson (1961) detected invasion of the oesophagus in 90 per cent of the specimens; in 60 per cent of the specimens there was microscopic spread of the disease beyond a 2·5-cm radius from the palpable edge of the main lesion. The high incidence of recurrence among patients with lesions of the cardia in our study could not be attributed to the adequacy of resection because histologically positive oesophageal margins were present in 36 per cent as compared with 40 per cent of patients with corpus tumours. One may speculate here that neoplasms of the cardia tend to cause skip intramural metastases and invasion of the peri-oesophageal tissues in the way that primary oesophageal neoplasms do, hence they ought to be treated with wider margins than corpus lesions.

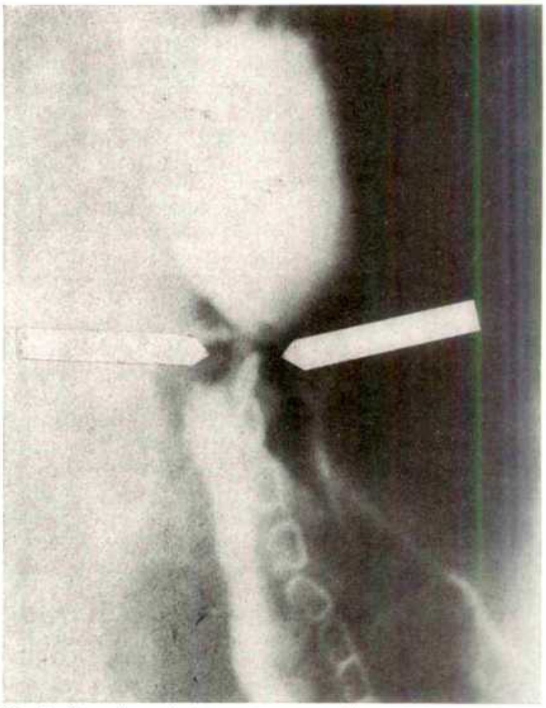

Fig. 1. Oesophageal obstruction caused by recurrence of a gastric neoplasm at the anastomosis following proximal subtotal gastrectomy.

Recurrences were more common in patients with early rather than advanced stage lesions. Patients with early stage disease live longer and have a greater chance of developing recurrence at the anastomosis, while stage III and IV patients usually succumb early due to distant metastases before the appearance of anastomotic recurrence. For the same reason the effect of recurrence on survival was far greater among patients with early rather than advanced stage disease. Studies conducted in our institution showed that surgical treatment makes a difference in patients with TNM stage I and II lesions only, while stage III and IV patients are seldom benefited by it (Papachristou and Fortner, 1979). Considering these facts and the poor prognosis of patients developing recurrence, prevention of this complication by adequate surgery is of enormous importance in patients with early stage disease.

The question as to what constitutes an adequate oesophageal resection in the treatment of gastric neoplasms is difficult to answer. Surgeons have traditionally used palpation and frozen section examination of the oesophageal margin to determine the adequacy of resection (Pack, 1949). It appears that both these methods can be inaccurate for two main reasons. First, the macroscopic boundaries of the neoplasm in the oesophagus rarely coincide with the microscopic ones, hence palpation can mislead the surgeon. Thus, the recurrence rate was not reduced significantly in our series when margins of 2–3 cm in length were obtained. These margins correspond to 4–6 cm *in vivo* (Miller, 1962). Even with macroscopic margins as long as 4–6 cm, i.e. 8–12 cm *in vivo*, recurrences were not prevented. Some of the patients with 4–6 cm margins had histologically positive margins despite the high levels of oesophageal transection. Secondly, the use of frozen section examination did not decrease significantly the incidence of anastomotic recurrence. Frozen section informs the surgeon whether or not tumour is present at the line of oesophageal transection. Frozen section does not detect skip submucosal lesions located above this level (Morson, 1961) or invasion of the peri-oesophageal tissues. All these facts suggest that palpation of the oesophagus above the tumour or frozen section of the oesophageal margin cannot determine accurately the adequacy of resection. What constitutes then an adequate margin?

The problem with comparing the various reports in regard to the size of oesophageal margins is that only a few take into consideration the fact that the oesophagus (Miller, 1962) and the rectum (Rosi, 1969) shrink to half their original size after resection and that it is almost impossible to reconstruct *in vivo* dimensions postoperatively (Payne and Bernatz, 1976). Thus, Humphrey and Kerstens (1976) believe that a 7-cm margin is the minimum requirement, while Payne and Bernatz (1976) consider a 4-cm margin as adequate. Both groups, however, recommend transection of the oesophagus at the level of the azygos vein if the tumour involves the cardia. Others (Garlock and Klein, 1954) recommend a supra-aortic anastomosis in such patients because transection of the oesophagus 3–6 cm above the lesion results in a high recurrence rate (Humphrey and Kerstens, 1976) despite the fact that a 6-cm margin usually includes all intramural disease (Miller, 1962). Recurrences in our series were prevented only with margins longer than 6 cm, which correspond to 12 cm *in vivo*. Margins of this size should probably be considered in the treatment of patients with early stage tumours and in those with primary neoplasms of the cardia since these are the patients who are particularly prone to anastomotic recurrence.

Patients developing anastomotic recurrence were rarely responsive to treatment. The only patients to benefit from it were those undergoing complete resection of the entire recurring process. Incomplete resections leaving tumour in the mediastinum were of no value. When resections were attempted in the face of advanced intrathoracic disease the mortality was high. Thus, resections should only be carried out if the tumour can be resected thoroughly with proper margins and no residual disease. Radiation therapy provided some palliation by alleviating dysphagia for a few months, although it failed to prolong the survival rate any more than other palliative methods such as oesophageal intubation or dilatation. For this reason radiotherapy ought to be reserved for those who cannot tolerate re-exploration and those with unresectable lesions.

Bilio-pancreatic bypass for obesity: I. An experimental study in dogs

NICOLA SCOPINARO, EZIO GIANETTA, DARIO CIVALLERI,
UMBERTO BONALUMI AND VIRGILIO BACHI*

SUMMARY

Bilio-pancreatic bypass is a new procedure that tries to obtain a maldigestion syndrome with selective malabsorption of the main high calorie foods. The operation consists of a gastric resection and division of the proximal jejunum just distal to the ligament of Treitz. A gastroentero-anastomosis is then constructed using the distal end of the transected jejunum, while the proximal jejunum is anastomosed to the side of the distal ileum.

An experimental study carried out on 12 dogs confirmed that the operation causes a selective malabsorption with loss of weight and no complications. On the basis of this study it is suggested that this procedure has the following advantages over jejuno-ileal bypass: (a) *normal absorption of bile salts, water and electrolytes;* (b) *slow recovery of absorption;* (c) *absence of a blind loop.*

JEJUNO-ILEAL bypass has become an established procedure for the surgical treatment of extreme obesity. Weight loss is satisfactory, but the operation is often followed by serious and sometimes fatal complications, such as intractable diarrhoea, electrolyte imbalance, hypovitaminosis, protein malnutrition, anorexia, nausea, vomiting, hepatic insufficiency, cholelithiasis, nephrolithiasis and polyarthritis. Some of these complications may be related to interruption of the enterohepatic bile salt circulation by the jejuno-ileal bypass; this interruption leads to the depletion of the bile salt pool, which favours the formation of gallstones (Wise and Stein, 1975; Scopinaro, Roda et al., 1976). Unabsorbed bile acids in the large bowel increase motility (Galapeaux et al., 1938; Meyer and McEwen, 1948), inhibit absorption (Mekhjian et al., 1968; Mekhjian and Phillips, 1970) and induce secretion of water and electrolytes (Mekhjian et al., 1971) causing diarrhoea and electrolyte imbalance.

The pathogenesis of nephrolithiasis after jejuno-ileal bypass is still controversial (Dickstein and Frame, 1973; O'Leary et al., 1974), but possible causes are the reduction of urine volume secondary to dehydration and hyperoxaluria due to excessive glycoxalate production from unabsorbed glycoconjugated bile salts in the colon (Wise and Stein, 1975). Moreover, the hepatic injury following intestinal shunt for obesity has been attributed to the hepatotoxic action of lithocholic acid (Drenick et al., 1970) and chenodeoxycholic acid (Sherr et al., 1974).

Malabsorption induced by jejuno-ileal bypass is extreme in the first months after operation, but the compensatory mechanisms quickly lead to the recovery of absorptive function (Scopinaro, 1974; Barry et al., 1977). As a result, a satisfactory final weight reduction necessitates exclusion of greater lengths of bowel, with an increased risk of complications (Jewell et al., 1975). Complications due to the blind loop include intussusception (Wise et al., 1976) and gastric hypersecretion (Buchwald et al., 1974; Danö and Van Nielsen, 1974; Scopinaro, Marugo et al., 1976; Solhaug and Schrumpf, 1976). The observations that hepatic injury does not occur after extensive small bowel resection (Kinney et al., 1962; Meyer, 1962; Bondat and Pisesky, 1967) and that it can be prevented after jejuno-ileal bypass by jejunostomy feedings (McClelland et al., 1970) suggest that a substantial role in the pathogenesis of liver damage must be attributed to the presence of a long intestinal loop excluded from the alimentary stream (Hollenbeck et al., 1975).

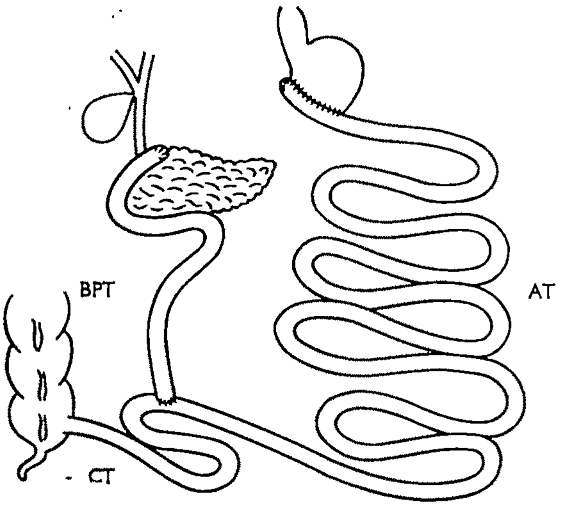

Fig. 1. Schematic representation of the operation of bilio-pancreatic bypass. BPT, Biliopancreatic tract; CT, common tract; AT, alimentary tract.

Bilio-pancreatic bypass is a new surgical procedure in which partial gastrectomy is performed, with closure of the duodenal stump. Gastrointestinal continuity is restored by a Roux-en-Y gastrojejunostomy, with the proximal end of the jejunum anastomosed to the distal ileum (*Fig.* 1). Three separate parts of the intestinal tract can then be recognized: the alimentary tract from the gastrojejunostomy to the jejuno-ileostomy; the bilio-pancreatic tract from the duodenal stump to the jejuno-ileostomy; and the common tract from the jejuno-ileostomy to the ileocaecal valve.

In the new anatomic situation the bilio-pancreatic secretion following meal intake reaches the distal ileum earlier than the undigested aliments which have to pass through a much longer intestinal tract. Provided that the ileal common tract is long enough to allow a normal absorption of bile salts, it is then

possible to obtain a fat and starch maldigestion leaving the enterohepatic bile salt circulation undisturbed.

Since the alimentary transit through nearly the entire small bowel is preserved, jejuno-ileal absorption of water, electrolytes and hydrosoluble vitamins is allowed, while negative effects and complications due to the presence of the excluded bowel are avoided.

The degree of malabsorption depends on the digestive capacity of jejuno-ileal enzymes, on the residual or postprandial bilio-pancreatic secretion which is present in the distal ileum when the aliments reach the anastomosis, on the length of the common tract and on the transit time. Each of these factors may vary after operation, but the essential maldigestion system, based on the difference between bilio-pancreatic and alimentary transit time, is very unkely to be influenced by compensatory mechanisms.

Bilio-pancreatic bypass should then have the following advantages: (*a*) a selective instead of indiscriminate malabsorption; (*b*) a slow rather than rapid recovery of absorptive function; (*c*) the absence of the long loop of excluded bowel. In order to test the hypothesis that these advantages, if present, avoid the complications of jejuno-ileal bypass, a series of experiments was performed in the dog. This animal was chosen because it has been shown that the operation of jejuno-ileal bypass is followed by the same complications in the dog as in man (Kremen et al., 1954; Bondar and Pisesky, 1967; McClelland et al., 1970; Salmon, 1971; Hollenbeck et al., 1975).

Materials and methods

Twelve mongrel dogs weighing between 15 and 20 kg were fed a daily ration of a commercial dog food adequate to keep a stable body weight. The ration was divided into two equal meals and given to the dogs for at least 15 days before operation.

After the abdomen had been opened and the viscera inspected, the length of the small intestine was measured along its mesenteric border from the ileocaecal valve to the ligament of Treitz. A three-quarters distal gastrectomy was then performed, the duodenal stump being closed and the jejunum divided 20 cm distal to the ligament of Treitz. An anticolic antiperistaltic gastroentero-anastomosis was made using the distal end of the transected jejunum. The proximal end of the jejunum was finally joined end to side to the ileum. The distance of the anastomosis from the ileocaecal valve was equivalent respectively to: one-third of the intestinal length (70 cm approximately, group I, 3 dogs); one-sixth of the intestinal length (35 cm approximately, group II, 4 dogs); one-twelfth of the intestinal length (20 cm approximately, group III, 3 dogs). In 2 dogs (group IV, control group) only a three-quarters gastric resection and Billroth II gastrojejunostomy was performed. Before closing the abdomen a liver biopsy and a bile sample were obtained.

Pre- and postoperative investigations included blood count, blood sugar, blood urea nitrogen, serum total protein, albumin, bilirubin and alkaline phosphatase, SGOT and SGPT, electrolytes (Na, K, Cl, Ca, Mg and P), determination of the prothrombin time and complete urine examination.

Intestinal absorption of fat was evaluated by determination of the daily faecal fat excretion (mean of three consecutive days); protein absorption was determined by the radioactivity in faeces during the 48 h following administration of ^{125}I-albumin (5 mCi) with meals. To estimate intestinal absorption of bile salts, 5 mCi of 1-(^{14}C)-glycine-glycocholate were added to a daily ration of food and the ^{14}C faecal excretion during the subsequent 48 h was determined.

After operation the dogs were recommenced on their standard diet with the exception of the 3 dogs in group III who received food *ad libitum*. During this period all the animals were weighed weekly and studied carefully to ascertain the number and consistency of stools. After the first month the daily food ration of dogs in groups I and II was increased progressively until no further weight loss occurred. In order to compare pre- and postoperative absorption studies, supplementary meals were given without varying the amount of food at each meal. During this second follow-up period group I, II and IV animals were weighed monthly and group III animals weekly. After 1 year all the long term survivor dogs (groups I, II and IV) were sacrificed under anaesthesia. Post-mortem examinations were performed in all dogs.

Results

During the entire course of the experiment the dogs in group I had one daily formed bowel movement. They lost a mean of 20 per cent of their original weight during the first month and stopped losing weight when fed with about 150 per cent of the preoperative diet. Group II dogs had 2–5 daily soft stools in the first week after operation. Subsequently they showed a decrease in the number of stools and those passed became firmer in consistency. After 2 months they did not differ from the group I animals, except that the stool weight was greater. The dogs in this group lost a mean of 35 per cent of their initial weight during the first month and their weight stabilized when their intake was 250 per cent of the preoperative daily food ration. Dogs in group I and group II continued to keep a stable weight on their standardized increased diet. Group III dogs exhibited after the operation a severe and persistent diarrhoea, with up to 15 liquid bowel movements per day. They appeared to eat and drink more than before surgery but, despite this, continuously lost weight with the onset of dehydration and malnutrition. All the animals died during the second postoperative month, having lost more than 50 per cent of their original weight. When appearing close to death they were sacrificed under anaesthesia.

Dogs in group IV (control group) had no variations in frequency, consistency or weight of bowel movements following the operation. They showed an average of 10 per cent weight loss immediately after operation, followed by a progressive weight gain that stabilized by the fourth month at around preoperative levels.

Absorption studies

Preoperative determinations of fat and protein absorption were normal (less than 5 per cent faecal excretion) in all dogs. Absorption tests were repeated in groups I, II and IV at 1, 6 and 12 months after the operation. No absorption studies were performed in group III dogs as watery diarrhoea made it impossible to collect stools. In group I dogs 24·2 ± 7·9 per cent (mean ± s.d.) of fat intake was excreted in the faeces, and this decreased to 21·2 ± 3·9 at 6 months and 18·6 ± 3·7 at 12 months (*Fig*. 2).

In group II dogs the fat excretion was nearly double (one month, 43·3 ± 12·1 per cent; 6 months, 35·0 ± 6·9 per cent; 12 months, 32·2 ± 7·2 per cent) (*Fig*. 3). In the control group the pre- and postoperative studies were similar. The average ^{125}I-albumin faecal excretion in groups I and II showed a similar trend, with the greater loss in group II dogs (*Figs*. 2 and 3).

Bile studies

Bile salt metabolism was explored by evaluating pre- and postoperative intestinal absorption and gallbladder bile composition. Bile acid intestinal absorption was determined in groups I, II and IV before operation and 1, 6 and 12 months after surgery. Faecal excretion was within normal limits (less than 5 per cent of administered dose) in all instances before and after operation.

Gallbladder bile specimens were obtained by direct puncture at operation and at sacrifice in all dogs. Additional gallbladder punctures were performed 1 month and 6 months after operation in 1 dog from group I and in 2 dogs from group II after surgical exposure under anaesthesia. No significant alterations in bile composition were found after operation in groups I, II and IV. Bile analysis in group III animals demonstrated a marked postoperative fall in bile salt concentration (preoperative, 35·4 ± 4·3 mmol/l; postoperative, 24·2 ± 8·1 mmol/100 ml).

Electrolyte studies

Serum electrolyte determinations, performed weekly during the first month and subsequently at 3, 6, 9 and 12 months after operation, showed no postoperative changes in groups I, II and IV, with the exception of a slight transient decrease of potassium and calcium serum levels in the animals in group II at 1 to 3 weeks postoperatively. Dogs in group III exhibited a progressive fall in serum electrolyte concentration. Major deficiencies were observed for potassium, calcium and magnesium.

Liver studies

Wedge biopsies of the liver were taken from all dogs at operation and at sacrifice; in 1 dog from group I and in 2 dogs from group II wedge biopsies were performed under anaesthesia at 1 month and 6 months postoperatively. The liver biopsies showed no morphological abnormality. Liver function, as determined by measurement of serum bilirubin and alkaline phosphatase, SGOT and SGPT and prothrombin time, was unaltered at 1, 6 and 12 months in groups I, II and IV. Liver function tests were within normal limits in group III dogs at the time of sacrifice, despite the state of cachexia due to malnutrition.

Other biochemical findings

Studies on blood cells, serum protein, blood sugar, blood urea nitrogen and urine examination, performed postoperatively at the same time intervals as the electrolyte studies, demonstrated no alteration in dogs in groups I, II and IV. However, group III animals developed a progressive anaemia, hypoproteinaemia, increased blood urea level and ketonuria.

Other observations

An endoscopic examination of the gastrojejunostomy with pH determinations was done under anaesthesia 6 months after operation in 1 dog from group I and in 1 dog from group II. The mucosa of the gastric stump, the stoma and the proximal tract of the jejunal loop appeared normal in both instances. The secretion was minimal and the pH ranged between 5 and 7.

Intestinal length measurements were performed in 3 dogs at 6 months and in all the long term survivors at sacrifice. Changes were observed only in animals in groups I and II, with no significant difference between the two groups. The mean length of the alimentary tract increased by 21 ± 5 per cent 6 months after operation and by 35 ± 12 per cent at 12 months (mean ± s.d.). The mean length of the common tract was increased by 47 ± 15 per cent at 6 months and by 58 ± 17 per cent at 12 months. Histological examination showed mucosal hypertrophy, which was more pronounced in the common tract. Neither elongation nor microscopical change was demonstrable in the bilio-pancreatic tract.

At post-mortem examination, no macroscopic abnormality was noted. Histological examination of selected organs, other than the intestine, was normal.

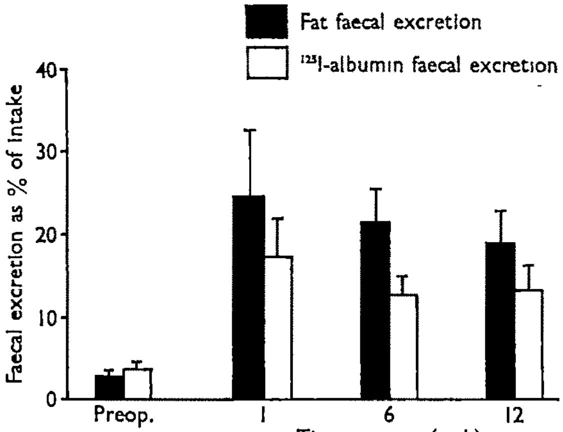

Fig. 2. Fat and protein malabsorption in dogs with one-third bilio-pancreatic bypass (group I).

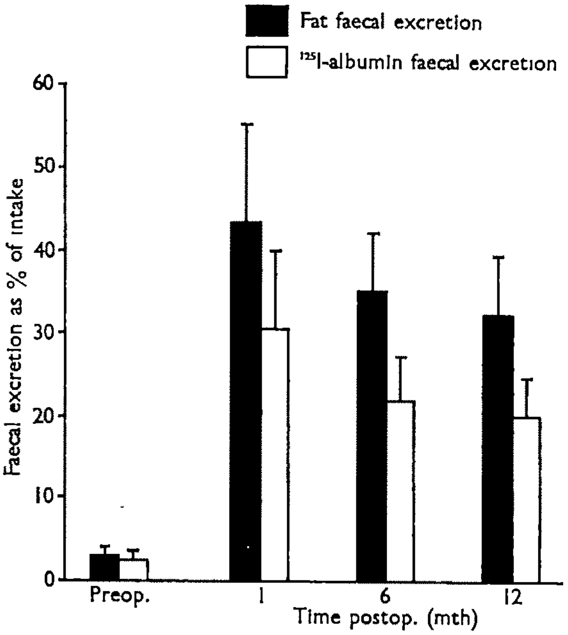

Fig. 3. Fat and protein malabsorption in dogs with one-sixth bilio-pancreatic bypass (group II).

Discussion

The main requirement of bilio-pancreatic bypass is that the ileal common tract is long enough to allow normal bile salt absorption. Three different experimental models were designed to assess the minimal length of this tract which would still prove adequate. Dogs in group III exhibited watery diarrhoea with altered bile acid metabolism, suggesting that a loop of distal ileum equivalent to one-twelfth of the total length of the small bowel is not sufficient for normal bile salt absorption. The experimental study was designed to demonstrate that bilio-pancreatic bypass causes selective malabsorption and to verify the absence of the complications and side effects which usually follow jejuno-ileal bypass.

The selective nature of the malabsorption due to the bilio-pancreatic bypass is shown in dogs in groups I and II by the absence of postoperative abnormalities, i.e. the number and consistency of stools, the serum electrolyte levels, the faecal excretion of bile salts and the gallbladder bile composition were all normal, while fat and protein intestinal absorption were reduced.

After jejuno-ileal bypass there is a tendency towards recovery of absorptive capacity after the first 6 months. The slow recovery of intestinal absorptive capacity after bilio-pancreatic bypass is suggested by the observation that animals in groups I and II, once they had lost weight, did not regain any significant weight even though they were kept for more than 10 months on the same diet. Despite malabsorption, no dog in group I or II exhibited postoperative diarrhoea or changes in serum electrolytes. Urinary or biliary calculi were never found at sacrifice. All the animals in groups I and II appeared active and in good health. Group III dogs appeared to have a serious bile salt malabsorption yet they had no functional or morphological signs of liver injury. This contradicts the theory that altered bile acid metabolism is an important factor in the pathogenesis of liver changes following jejuno-ileal bypass. On the contrary, our observations support the hypothesis that liver injury is due to the presence of a long intestinal loop excluded from the intestinal stream.

Bilio-pancreatic bypass is similar to the Mann–Williamson operation (Mann and Williamson, 1923) for the experimental production of peptic ulcer. The effect of gastrectomy with and without vagotomy on the course of the Mann–Williamson dog was investigated by Oliver (1949, 1951), who found that none of 6 animals with vagus section plus gastrectomy developed ulcers, while all 4 dogs with subtotal gastrectomy alone did develop ulcers. In contrast, Storer et al. (1950) showed that simple antrectomy was effective in preventing ulcer formation in 4 of 6 dogs with the Mann–Williamson operation. In our experimental series a three-quarters distal gastric resection has proved to be a sufficient measure to avert the risk of jejuno-ileal peptic ulceration during the 12-month follow-up.

From the results of this experimental study it is suggested that the operation of bilio-pancreatic bypass with insertion of the bypass into the ileum at a distance from the ileocaecal valve equivalent to one-sixth of the intestinal length allows adequate weight loss with minimal complications. It is recommended that this procedure overcomes many of the problems associated with the operation of jejuno-ileal bypass in the treatment of obesity.

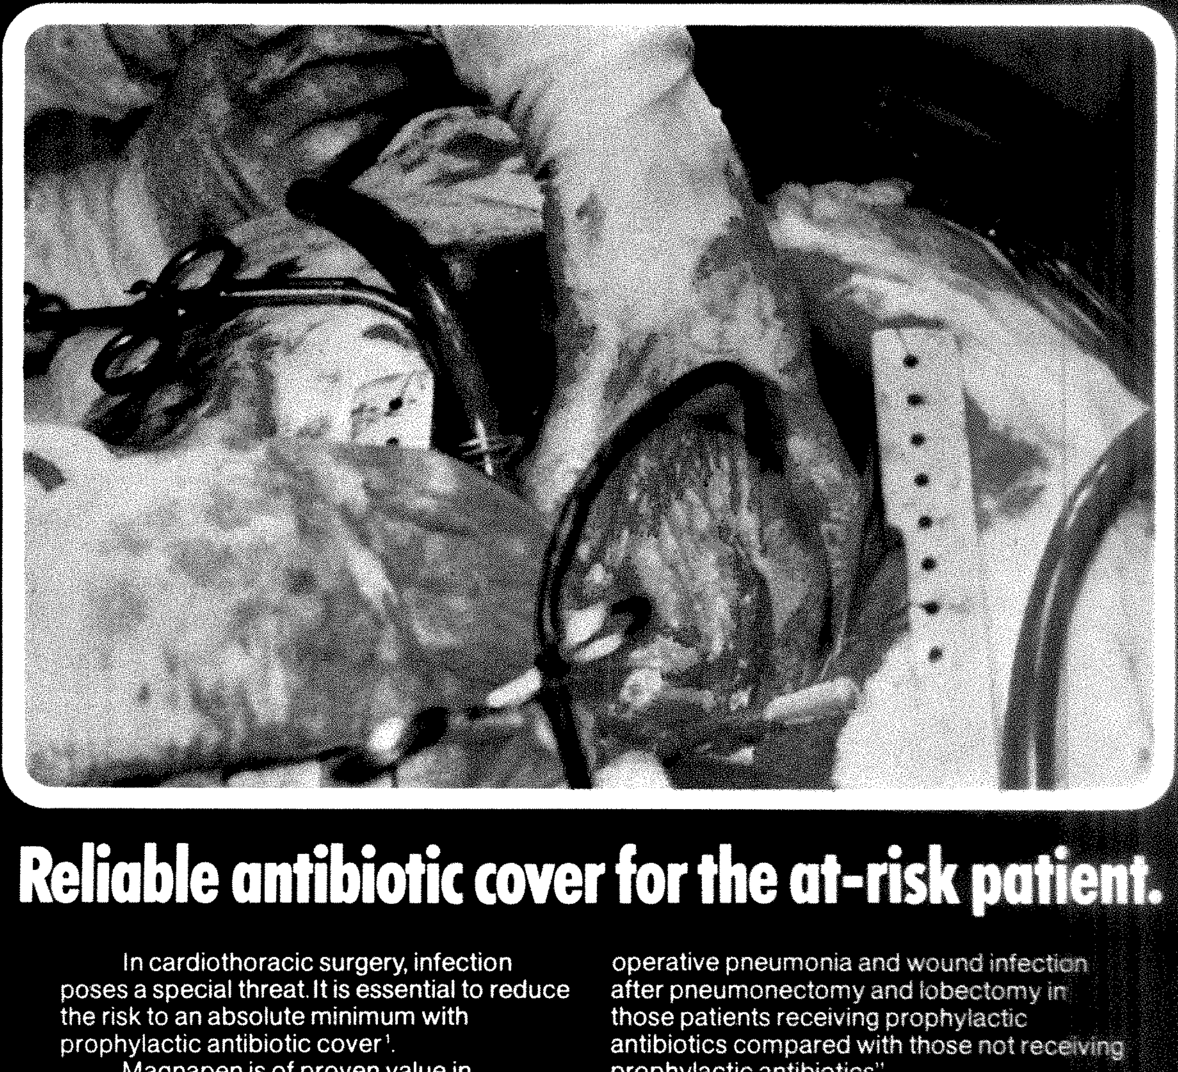
Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted 'Magnapen' containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post-operative chest and wound

Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial q.i.d. Children: 2-10 years [illegible] adult dose. Under 2 years [illegible] adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL 0038/5001, 5009
Contra-indications: Penicillin hypersensitivity, ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product

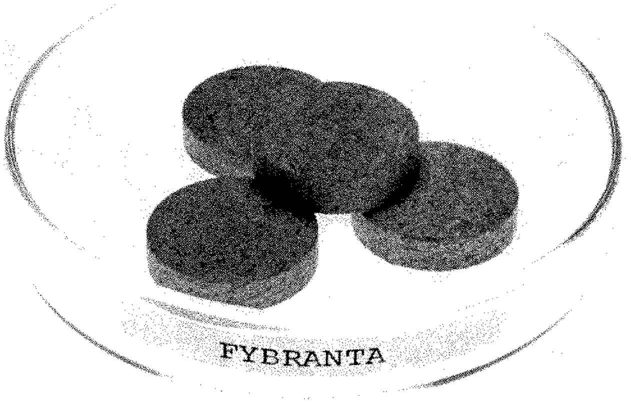
FYBRANTA
cereal fibre



The only fibre
that does all it should

Fybranta contains unprocessed cereal fibre which has been clinically proved more effective than other widely used fibre treatments. Only cereal fibre significantly reduced transit time[1,2] and also lowered intraluminal pressure when tested against other substances[2]. In addition, Fybranta was shown to be effective in increasing stool weight[1].

Bilio-pancreatic bypass for obesity: II. Initial experience in man

NICOLA SCOPINARO, EZIO GIANETTA, DARIO CIVALLERI, UMBERTO BONALUMI AND VIRGILIO BACHI*

SUMMARY

After a successful trial of bilio-pancreatic bypass in dogs, a clinical study has been completed in 18 patients followed for more than 1 year. The operation has been modified to achieve the best weight reduction, and forming the bilio-pancreatic tract of equal length to the alimentary tract with a short common ileal tract, the average weight loss as a percentage of the preoperative body weight was 24·1 ± 5·4 per cent (mean ± s.d.) at 6 months and 33·7 ± 4·1 per cent at 12 months. The only immediate complication was a wound dehiscence, and there were no late complications. Liver function studies showed the absence of hepatic deterioration and liver biopsies showed improvement of liver morphology 1 year after the operation. It is suggested that this procedure may be an alternative to jejuno-ileal bypass in the management of obesity.

THE operation of bilio-pancreatic bypass has been described in dogs (Scopinaro et al., 1979) and found to produce selective malabsorption with good weight loss. In this operation a partial gastrectomy is performed with closure of the duodenal stump. The jejunum is transected 20 cm distal to the ligament of Treitz and a gastrojejunostomy is performed using the distal part of the Roux loop. The proximal part of the jejunal loop is anastomosed to the distal ileum. The main feature of this arrangement is that the separate passage of aliments and bilio-pancreatic secretion in the distal ileum makes it possible to obtain a fat and starch maldigestion leaving the enterohepatic bile salt circulation undisturbed. Animal studies suggested that this procedure produces a selective rather than indiscriminate malabsorption, a slow rather than rapid recovery of absorptive function and no complications from an excluded intestinal loop. This study describes our experience with 18 patients who had this operation to treat gross obesity.

Patients and methods

Eighteen patients whose weight had been 45 kg above their ideal weight for the previous 5 years, and who had been recommended to have a weight-reducing operation, agreed to have a bilio-pancreatic bypass procedure after the experimental nature of the operation had been fully explained. Each patient had failed to reduce weight by non-operative methods and no medical cause for their obesity had been found. All patients were under 50 years of age and had no other disease which might increase the operative risk. All patients were emotionally stable and intelligent enough to understand the risk of the operation; all had agreed to cooperate in the studies and the prolonged follow-up. The details of the 18 patients are shown in *Table I*. The operative technique was essentially the same as that described in dogs (Scopinaro et al., 1979) with the following differences: in the first 3 patients a selective vagotomy was added to the gastrectomy; a retrocolic gastroentero-anastomosis was made in 10 patients; four types of operation were tested by varying the length of the three components of the small gut (*Fig.* 1). Four patients had a bilio-pancreatic bypass, with a bilio-pancreatic tract of 30 cm and a common ileal segment equivalent to either one-seventh or one-tenth of the small bowel total length (group I). Two patients had a bilio-pancreatico–jejunal bypass in which the jejunum was transected 100–200 cm from the ligament of Treitz and a one-seventh common ileal segment formed (group II). Five patients had a bilio-pancreatico–jejunal bypass in which the small intestine was divided at its mid point so that the entire jejunum was excluded and the bilio-pancreatic and the alimentary tracts were of equal length, while the common ileal segment was equivalent to either one-seventh or one-tenth of the small bowel total length (group III). Group IV patients ($n = 7$) had a bilio-pancreatico–jejunal bypass which was identical to group II except that the common ileal segment had a fixed length of 50 cm.

Table I: CLINICAL DETAILS OF 18 PATIENTS WHO UNDERWENT BILIO-PANCREATIC BYPASS

Sex	Age (yr)	Height (cm)	Weight (kg)	Follow-up (mth)
F	43	152	105·0	22
M	38	178	132·0	22
F	30	165	137·2	21
F	36	154	99·9	20
M	32	175	149·0	19
F	25	153	92·9	18
F	17	164	110·0	17
F	37	155	102·0	17
F	28	160	137·6	16
F	30	153	115·0	16
M	34	177	122·6	16
F	36	166	137·3	15
F	49	165	136·7	15
F	45	155	131·8	15
M	33	182	122·2	15
F	36	150	150·0	15
F	27	163	103·0	15
M	30	175	120·0	14
Mean	34	163·4	122·5	17

The patients were seen for at least 14 months after the operation and their weight loss was monitored. Blood studies, performed preoperatively and at 1, 4 and 12 months after the operation, included serum electrolytes, total protein and albumin, blood urea nitrogen, blood sugar, blood sedimentation rate, blood count and serum cholesterol. Liver function tests were performed preoperatively and at 1, 4 and 12 months after the operation. These tests included serum bilirubin, blood ammonia, serum alkaline phosphatase, bromsulphthalein retention test (BSP), thymol turbidity, serum fibrinogen, prothrombin time and SGOT and SGPT. In addition, a wedge biopsy of the liver was performed at the operation and subsequently percutaneous needle biopsies were carried out at 1, 4 and 12 months postoperatively.

Because of the resemblance of this operation to the Mann–Williamson procedure for the experimental production of an ulcer, basal acid output was determined preoperatively and at 1, 4 and 12 months after the operation. In order to be certain that a peptic ulcer was not developing, gastroscopy was performed at 4 and 12 months after the procedure. On each occasion a gastric mucosal biopsy was performed.

Results

Recovery from the operation was quick and uneventful in all but one patient, who had a wound dehiscence which required resuture. No patient required dietetic or pharmacological management during the follow-up period. All patients had a normal appetite and, when left on a free diet after discharge from the hospital, rapidly returned to their preoperative eating habits with a calorie intake equal to or higher than before the operation. After return of bowel function and during the follow-up period patients passed an average of three to four soft to formed stools per day. No patient developed watery diarrhoea. Soon after discharge from hospital all patients were able to return to their normal occupations. The only complaint during the whole of the follow-up period was a transient anorectal irritation, complained of by 5 patients; this disappeared spontaneously during the second postoperative month.

Weight loss in group I (*n* = 4) was poor (*Fig.* 2) compared with the other groups. After bilio-pancreatico-jejunal bypass (groups II and III) the mean weight loss was 21·8 ± 4·3 per cent (mean ± s.d.) of the original weight at 6 months and 26·2 ± 2·6 per cent at 12 months (*Fig.* 3), while in group IV the weight loss was 24·1 ± 5·4 per cent and 33·7 ± 4·1 per cent at 6 and 12 months postoperatively (*Fig.* 4).

No patient showed any abnormality in serum electrolytes, total protein and albumin, blood urea nitrogen, blood sugar, blood sedimentation rate or blood count in the postoperative period.

One patient was hypercholesteraemic before operation. The average percentage reduction for the 18 patients from the preoperative cholesterol level was 18·8 ± 12·2 per cent at 1 month, 24·8 ± 11·8 per cent at 4 months and 35·0 ± 11·1 per cent at 12 months, with normalized values in the above-mentioned patient.

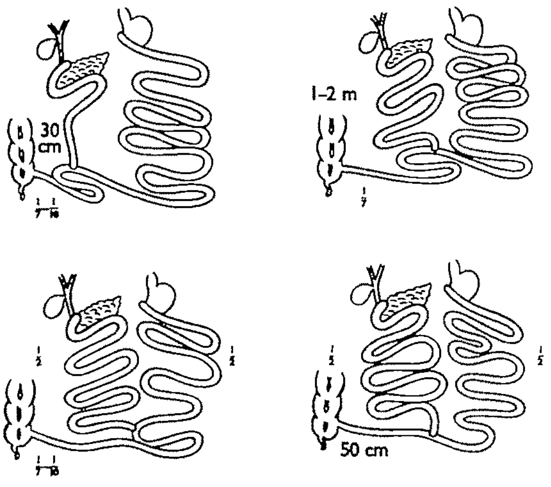

Fig. 1. The operative procedures performed in the 18 patients who had bilio-pancreatic bypass: *a*, group I (*n* = 4); *b*, group II (*n* = 2); *c*, group III (*n* = 5); *d*, group IV (*n* = 7).

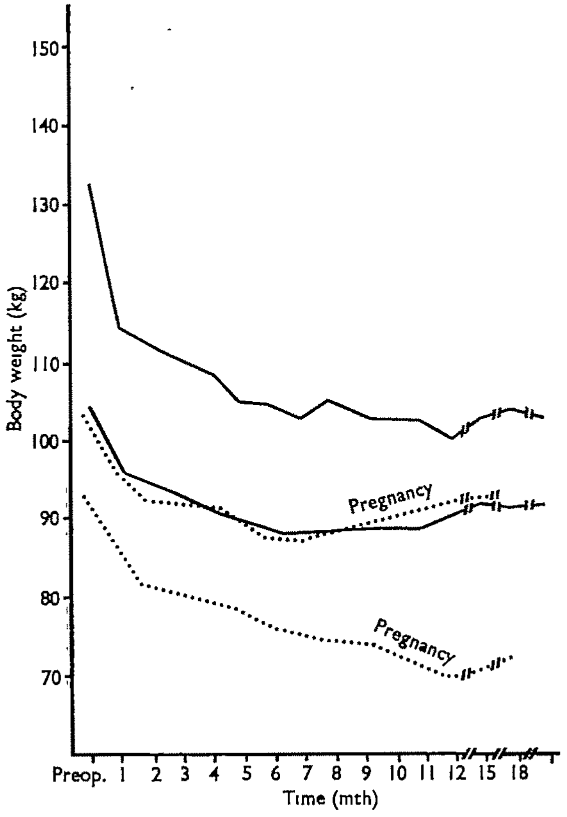

Fig. 2. The weight reduction of the 4 patients in group I who had a bilio-pancreatic bypass alone.

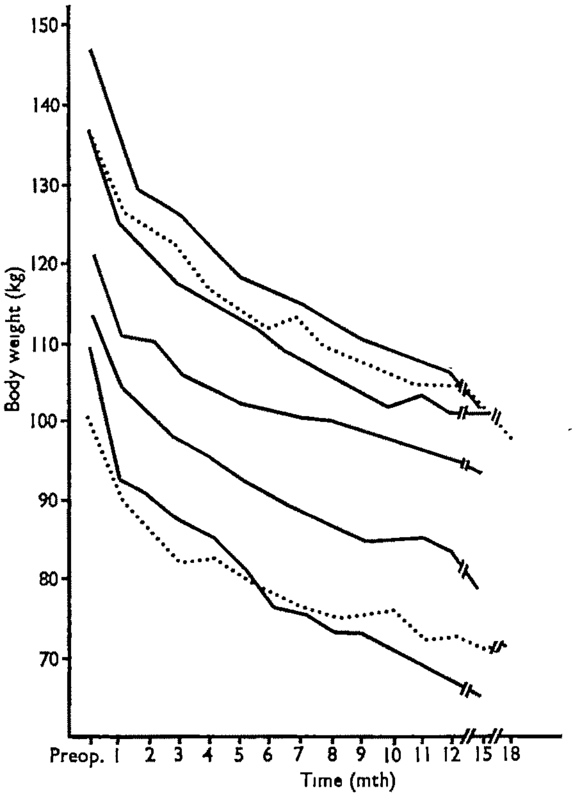

Fig. 3. The weight reduction of the 7 patients in groups II and III who had a bilio-pancreatico-jejunal bypass.

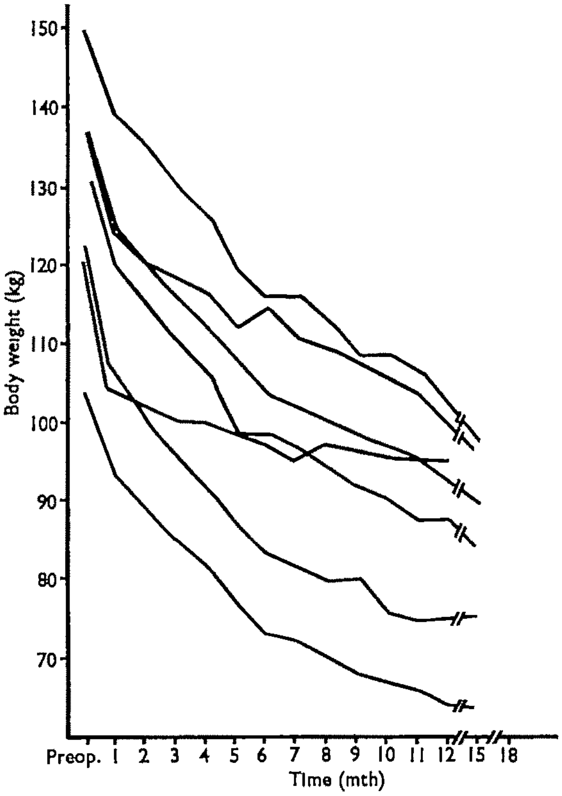

Fig. 4. The weight reduction in the 7 patients in group IV who had a bilio-pancreatico–jejunal bypass with a standard 50 cm common ileal segment.

Liver function tests revealed no change from the preoperative pattern at 1 and 4 months after the operation. As is common in obese subjects, there was an increase in the BSP retention in 12 of the 18 patients preoperatively and 5 patients had abnormal transaminase levels before operation. Twelve months after the operation there was a marked improvement in the liver function tests of those patients with abnormal preoperative studies. The wedge liver biopsy performed at operation demonstrated fatty metamorphosis and portal tract inflammation in 16 of the 18 patients. In the subsequent percutaneous needle biopsies of the liver an increase in fatty metamorphosis was never found. A striking improvement in liver morphology was observed in all the 12-month studies.

The mean reduction in basal acid output after bilio-pancreatic and bilio-pancreatico–jejunal bypass was 83 per cent at 1 month, 85 per cent at 4 months and 97 per cent at 12 months. The fall in basal acid secretion did not seem to be influenced by vagotomy. Gastroscopy showed a normal gastrojejunal anastomosis; the biopsies taken at the time of the gastroscopy showed no significant abnormality.

Discussion

The early experience of the use of bilio-pancreatic bypass confirms the experimental studies in dogs, namely that this procedure can be performed safely and without major complication. The absence of the negative effects which usually follow jejuno-ileal bypass is easily explained by the absence of the two main defects of the classic operation, that is: (*a*) the indiscriminate malabsorption, with the interruption of the enterohepatic bile salt circulation; (*b*) the long excluded intestinal loop (Scopinaro et al., 1979). The risk of a peptic ulcer occurrence at the gastrointestinal anastomosis appears unlikely, and this is undoubtedly due to the gastrectomy which is performed as part of this procedure.

In conclusion, it can be suggested that bilio-pancreatic diversion is an alternative clinical approach to jejuno-ileal bypass for the treatment of obesity The rate of weight loss appears to be more sustained in the patients with a shorter distance from the entero-enterostomy to the ileocaecal valve and with a longer jejunal loop excluded from the alimentary stream. However, the exact length of the common ileal segment and the length of jejunum in the bilio-pancreatic tract required to achieve maximum weight reduction with minimum complications have yet to be determined.

A 10-year survey of large bowel carcinoma at Groote Schuur Hospital with particular reference to patients under 30 years of age*

M. S. ELLIOT AND J. H. LOUW†

SUMMARY

In a 10-year survey of large bowel carcinoma at Groote Schuur Hospital 926 cases were studied retrospectively. A marked difference was seen in both the age of presentation and histological differentiation in two different racial groups. All patients who were 29 years of age or less at the time of presentation have been studied in detail. Predisposing factors, symptomatology, treatment, pathology and prognosis are discussed. It is apparent that large bowel carcinoma in the young has a very poor prognosis.

THE geographical distribution and epidemiology of large bowel carcinoma are currently of great interest. Burkitt (1971) made a strong argument in favour of environmental and dietary carcinogens as a cause of this condition. The highest incidence appears to be in the Western world whereas low and very low incidences have been reported from Africa (Bremner and Ackerman, 1971; Ngala Kenda, 1976). The greatest incidence among both males and females is in Scotland. For males New Zealand is fourth and for females New Zealand is second (Enker, 1978). The purpose of the present study was to compare the features of carcinoma of the large bowel in two different groups; Caucasian patients and patients of mixed race, both living in the same area.

The Caucasians are descendants of immigrants from Holland, France, Britain and Germany who came to the Cape in the seventeenth and eighteenth centuries.

The group of mixed race are of diverse ethnic origins. They are descendants of the Hottentots (a primitive indigenous race of the Cape), slaves from West Africa and the East Indies, Caucasians and contract labourers from Malaya.

Patients and methods

Groote Schuur Hospital is a teaching hospital with 1380 beds serving patients of all races. The case reports of all patients admitted to the Hospital from June 1967 to June 1977 were reviewed and 941 cases of large bowel carcinoma were found, of which 926 gave adequate documentation for a retrospective study. Of these, 591 were Caucasians, 325 were of mixed race and only 10 were black. In view of their small number, black patients have been excluded from this study; this low figure can be explained on the basis of two factors. First, the disease is uncommon in this racial group (Bremner and Ackerman, 1971) and secondly the black population of Cape Town is considerably lower than that of other areas of South Africa.

Results

Age incidence

The ages of the Caucasian patients varied from 24 to 99 years, with the majority presenting in the seventh decade of life (median age 66 years). This is similar to the incidence in most Western series (Goligher, 1941).

The ages of the patients of mixed race ranged from 12 to 99 years, with the peak incidence in the fifth and sixth decades (median age 52 years).

It can be seen that there is a very striking difference in the median age of presentation between the two groups (*Fig.* 1). Other authors (El Masri and Boulos, 1975; Ngala Kenda, 1976) have also shown that non-Caucasian patients tend to present at an earlier age. In this study the difference cannot be explained on the basis of the mixed race population being younger than the Caucasian. The South African life tables show an almost identical life expectancy in the two groups after the age of 30 years (*Fig.* 2).

When reviewed by decades, 72 patients of mixed race (22·5 per cent) were 40 years of age or under, compared with 29 Caucasian patients (5 per cent) ($\chi^2 = 60$, $P < 0{\cdot}001$).

Eight per cent of the patients of mixed race were 29 years or under, a figure considerably higher than that given in any Western series (Rankin and Comfort, 1929; Pennington, 1963).

Sex incidence (*Table I*)

In the Caucasian patients the male to female ratio was 2 : 3 for colonic lesions, but 5 : 4 for rectal lesions, figures which correlate well with Western series (Smiddy and Goligher, 1957). Both sex ratios were reversed in the mixed race group and Bremner and Ackerman (1971) reported similar findings. They found that colonic carcinoma in South African blacks was more common in males than in females, whereas the incidence of rectal carcinoma was equally distributed between the sexes.

Anatomical distribution (*Table II*)

The anatomical distribution of the carcinoma by site in both race groups correlated well with most Western series (Smiddy and Goligher, 1957), with the exception of the high incidence of anal carcinoma in the mixed race group (5·5 per cent). However, Ngala Kenda (1976) from Zaire described the incidence of anal carcinoma as 10 per cent in blacks and El Masri and Boulos (1975) from the Sudan, reported a surprisingly high figure of 20 per cent in blacks. There appears to be no obvious explanation for this.

Synchronous lesions were seen in 2·8 per cent of Caucasian patients and 3·0 per cent of mixed race patients. These figures are similar to the incidence reported by most other authors (Goligher et al., 1951).

Pathological staging and differentiation

There was no statistical difference in the staging between the two groups, with the distribution being similar to most Western series (*Table III*). There was

a marked difference in the overall incidence of mucinous adenocarcinomas in the two groups—5 per cent of the Caucasians and 16 per cent of those of mixed race ($\chi^2 = 60$, $P<0{\cdot}001$). It is probable that at least part of the explanation for this is that the mixed race group were as a whole younger than the Caucasians. Davey (1968) found that mucinous carcinoma of the large bowel was particularly common in the African and this finding was supported by Ngala Kenda (1976), who found a 26 per cent incidence. However, again it would seem that the younger age group in these studies played an important role in the increased incidence.

Patients aged 19 years or less (*Table IV*)

There were 4 patients in this group, all of mixed race, with no family history or predisposing disease in any of them. The duration of symptoms varied from 3 days to 3 months. In 3 of the 4 patients the preoperative diagnosis was tuberculosis; the diagnosis in the fourth patient was acute appendicitis. In each case the tumour was resected and pathological examination showed all tumours to be mucus-forming lesions, indicating a very poor prognosis.

All patients were followed up until death and the longest survival time was 26 months.

Patients aged 20–29 years

There were 25 patients in this group of whom 22 were of mixed race and 3 Caucasian. There was no family history of bowel disease in any of the patients. None of the patients of mixed race had predisposing disease, whereas one Caucasian patient had long standing ulcerative colitis. The sex incidence and anatomical distribution were unremarkable, but the incidence of tumour resectability in this group was 42 per cent, compared with an overall figure of 82 per cent. The average duration of symptoms was 5 months, with a palpable mass being found in 64 per cent of cases.

Ten of this group of young patients (40 per cent) suffered a delay of between 1 and 18 months whilst investigations for suspected peptic ulcer disease were performed. Rectal examination would have revealed the diagnosis in 4 of these patients. The Dukes' pathological staging details are shown in *Table V* and histological differentiation in *Table VI*. The prognosis in general correlated more closely with the histological grading than with the pathological staging, full details of follow-up according to differentiation being shown in *Table VII*.

Discussion

Carcinoma of the colon and rectum is the most frequently diagnosed gastrointestinal malignancy regardless of age. Although it has been described in a stillborn (Ahfeld, 1880), the youngest documented patient was a 9-month-old girl (Kern and White, 1958). Approximately 1 per cent of all malignant growths of the large bowel are in persons under 30 years of age (Recio and Bussey, 1965; Hardin, 1972). According to some authors the prognosis of large bowel carcinoma is independent of age (Roth-Moyo et al., 1968; Hardin, 1972). However, our findings (*Fig.* 3) and those of other series (Recio and Bussey, 1965; Van Langenberg and Ong, 1972; Andersson and Bergdahl, 1976) would appear to refute this. In our series 88 per cent of patients under 30 years of age were of mixed racial origin. Chabalko and Fraumeni (1975) in the United

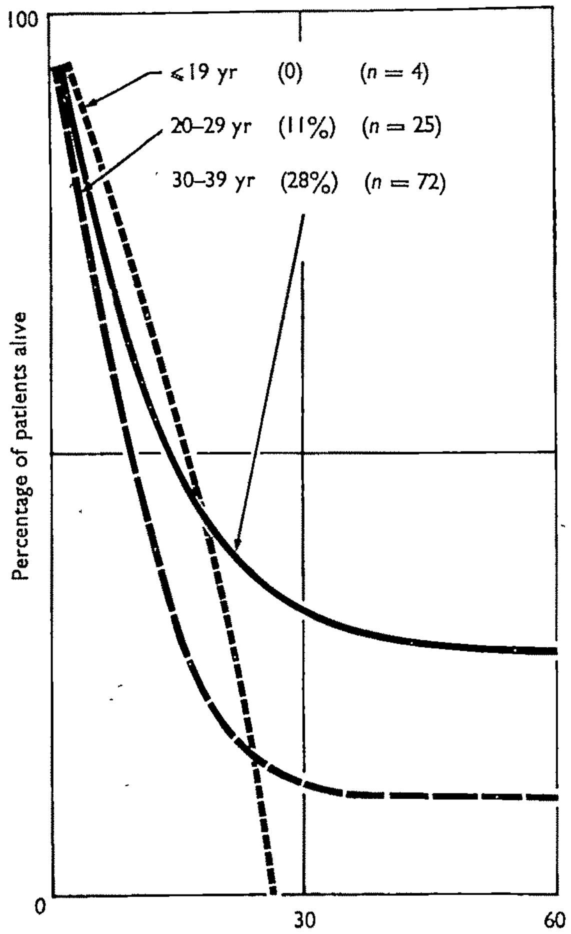

Fig. 3. Crude survival figures from 0 to 60 months for patients aged 12–39 years.

States also showed that the mortality from colorectal carcinoma in males under 20 years was four times higher amongst non-Caucasians than Caucasians.

None of our patients under 30 years of age had a family history of colorectal carcinoma. Van Langenberg and Ong (1972) likewise found no family history in 21 patients under 25 years of age.

The symptoms and their duration appear to be the same for young and old patients; however, in the younger age group the diagnosis of carcinoma is seldom entertained. Muir (1956) found that pain was a common feature with carcinoma of the right colon and that it tended to be situated in the epigastrium, with a definite relationship to meals, or to be located as pain in the appendicular region. This is supported by our finding that 10 of the 25 patients under 30 years of age were investigated for peptic ulcer disease for periods of 1 to 18 months before the correct diagnosis was made. One of our patients (S. B., *Table IV*), previously reported by Smith et al. (1976), underwent an emergency operation for abdominal pain. An appendicectomy was performed through a paramedian incision and the cause of the pain, a constricting carcinoma of the descending colon, was not detected. Many cases of large bowel carcinoma mimicking appendicitis have been recorded in children (Sessions et al., 1965; Andersson and Bergdahl, 1976). In these cases the symptoms are due to the increased intracolonic pressure which distends the caecum giving rise to localized tenderness in the right iliac fossa. It is therefore important if the history is at all atypical and the appendix is found to be normal at laparotomy that careful palpation of the colon and rectum be carried out.

In this series young patients had a very poor prognosis, with a lower incidence of resectability, despite a duration of symptoms similar to the other age groups (*Fig.* 3). This is largely due to the high incidence of mucin-forming tumours (*Table VI*); indeed all of our patients under 20 years of age had mucin-forming tumours. The incidence of mucin tumours appears to be higher than in similar age groups in Western populations (Coffey and Cardenas, 1964; Miller and Liechty, 1967). This would suggest that non-Caucasian

    1 alive at 6 mth (irresectable)
    1 alive at 4 mth (resected)

patients have a higher tendency to develop tumours of this type. Pillay et al. (1978) reviewed large bowel carcinoma in South African blacks under the age of 25; in all cases the tumours were shown to be mucus-forming. Middlekamp and Haffner (1963) reviewed microscopic sections of 27 published cases of carcinoma of the colon in children and found signet ring cells in 13 (47 per cent), i.e. ten times more frequently than in adult series, where the corresponding figure is 5 per cent (Hoerner, 1958).

When analysed by decades to 40 years there appeared to be only minimal differences in the Dukes' staging (*Table VI*). However, when the histological differentiation was reviewed there was a very dramatic change in the incidence of mucin-secreting carcinomas (*Table VI*). When the 5-year survival figures were reviewed, there was a very close correlation between tumour differentiation and 5-year survival. All our patients under 20 years had mucoid tumours and all were dead within 26 months. These depressing figures appear to be typical for this age group. Andersson and Bergdahl (1976) studied all published cases of large bowel carcinoma in children under 15 years and showed the 5-year survival rate to be 2·5 per cent. All patients under 30 years with poorly differentiated or mucin-secreting tumours were dead within 5 years, whilst those with well or moderately differentiated tumours were all alive at 5 years.

Conclusions

Large bowel carcinoma in patients of mixed race under 30 years of age is not rare. There appears to be a very striking difference in the median age of presentation between Caucasian and mixed race patients. Any young patient with abdominal pain, rectal bleeding or change in bowel habit should be evaluated with this in mind. The extremely poor prognosis in the young is due to the high incidence of mucin and undifferentiated tumours.

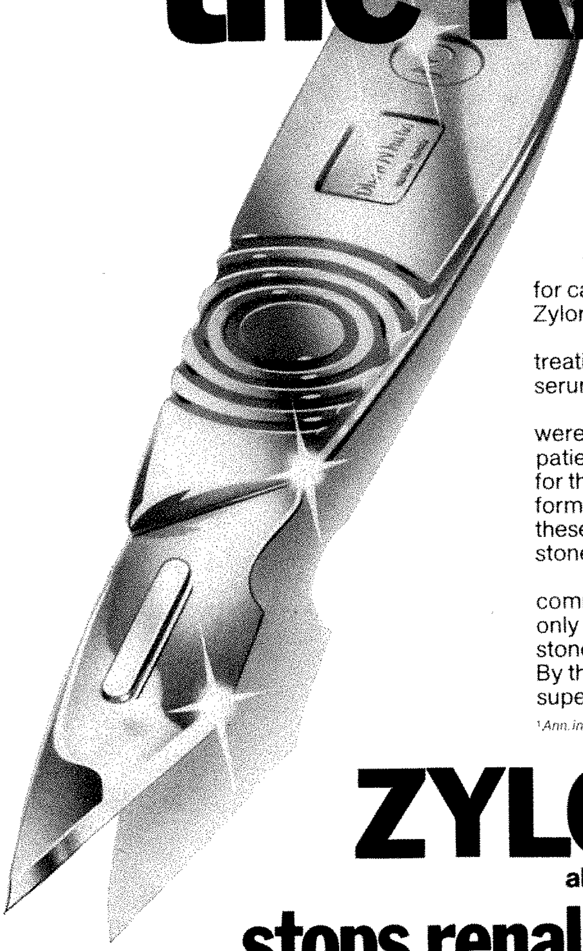
mightier than the knife



Now there is a practical alternative to surgery for calcium renal lithiasis: long-term prophylaxis with Zyloric.

Zyloric has proved effective in preventing and treating calcium renal lithiasis in patients with raised serum or urinary uric acid.

In a recent trial,[1] 48 patients with hyperuricosuria were treated with Zyloric for an average of 3.88 patient-years. The number of renal stones predicted for this period was 94.9. The actual number of stones formed was 8. Prior to treatment with Zyloric, half of these patients were hospitalised because of stone disease.

A leading article[2] in the *British Medical Journal*, commenting on another clinical paper[3] stated "...the only criterion of success in the treatment of calcium stone disease is total cessation of stone formation. By this criterion, allopurinol (Zyloric) was greatly superior to the placebo."

[1] *Ann. intern. Med.* (1977), **87**, 404. [2] *Brit. med. J.* (1977), **2**, 1302. [3] *J. Urol.* (1977), 117, 690.

ZYLORIC-300

allopurinol BP Wellcome

stops renal stones starting

Indications: Conditions of excess body urate including gouty arthritis. Prophylaxis of calcium renal lithiasis in patients with raised serum or urinary uric acid. **Dosage:** The average adult dose is one Zyloric-300 tablet daily, plus an anti-inflammatory agent or colchicine for at least one month. Dosage should be adjusted by monitoring serum uric acid until the required level is attained. It has rarely been found necessary to exceed 900 mg per day. Children, 10-20 mg/kg bodyweight/day. **Contra-indications:** None, other than known intolerance to Zyloric. **Precautions:** If Puri-Nethol* (6-mercaptopurine) or Imuran* (azathioprine) is given concurrently with Zyloric, the dose of Puri-Nethol or Imuran should be reduced to one quarter of the usual dose. Caution should be observed in pregnancy. Zyloric is not a treatment for acute gout, but prophylactic treatment with Zyloric may be started at the same time as anti-inflammatory treatment. **Side-effects:** These are usually rare and mostly of a minor nature. They include skin reactions, generalised hypersensitivity, gastro-intestinal disorders, blood and lymphatic disorders. **Presentation:** Zyloric-300* is available as 300 mg scored, creamy-white tablets in packs of 28. Basic NHS cost: £5.96 per pack. PL 3/0092. Also available: 100 mg tablets in bottles of 100. Additional information about Zyloric* (allopurinol) is available on request.

Creating the healing environment of the future.

By a unique mechanical action Debrisan removes from the wound those substances which normally complicate wound healing, such as bacteria and wound debris.

Pain, oedema and malodour are quickly reduced. Healing can now occur in an ideal environment. Fast.

Use Debrisan on all moist suppurating wounds such as pressure sores and leg ulcers.

Patients can enjoy the benefits of the healing environment of the future.

Today.

Total excision or restorative resection for carcinoma of the middle third of the rectum

R. J. NICHOLLS, JEAN K. RITCHIE, JANE WADSWORTH AND A. G. PARKS*

SUMMARY

Restorative resection is being used increasingly for carcinoma of the mid rectum but it is not yet certain whether this operation is as curative as total excision. Between 1963 and 1972, 209 patients left St Mark's Hospital after a radical operation for a single rectal carcinoma situated between 8 and 12 cm from the anal verge. A total of 199 patients was followed up for 5 years. Of these, 112 had been treated by total excision of the rectum and 87 by restorative operation. Survival was correlated with the Dukes' stage, histological grade and extent of local spread in the two groups.

There was no significant difference in 5-year survival after either total excision or restorative resection for Dukes' B (74 per cent, 71 per cent respectively) or average grade (61 per cent, 73 per cent respectively) tumours. Patients with Dukes' C tumours fared better when treated by restorative resection (36 per cent, 63 per cent), probably due to fewer high grade tumours in the restorative group (38 per cent, 18 per cent). Combining two variables, survival was not significantly different for patients with Dukes' B tumours of average grade (69 per cent, 62 per cent) or for Dukes' C tumours of average grade (48 per cent, 76 per cent). When the three pathological variables were combined, there was an improved survival after restorative resection for some pathological combinations.

It is concluded that restorative resection for carcinoma of the mid rectum is as curative as total excision in terms of 5-year survival.

THIRTY years ago total excision of the rectum was the accepted treatment for rectal carcinoma. During the 1940s, resection with restorative anastomosis began to be established as an alternative (Dixon, 1948; Lloyd-Davies, 1948; Mayo and Fly, 1956) and has since been used increasingly for growths of the upper rectum (Lockhart-Mummery et al., 1976). Since 1973 less than half of the patients undergoing operation for rectal carcinoma at St Mark's Hospital have required a permanent colostomy. This is largely because the scope of restorative resection has been extended to include tumours of the middle and occasionally of the lower third of the rectum. It is important to know whether these operations are as curative as rectal excision for tumours at these sites. For upper rectal tumours, Glenn and McSherry (1966) found that the 5-year survival rate with anterior resection was as good as with excision, but there is no evidence that this is true for tumours at lower levels.

In this retrospective study the results—expressed by 5-year survival rates—were compared in patients with carcinoma of the mid rectum treated either by rectal excision or by restorative procedures. Since, however, there is a tendency for more locally extensive and more undifferentiated tumours to be treated by excision (Slanetz et al., 1972; Lockhart-Mummery et al., 1976), overall results would be biased in favour of resection. Using Dukes' classification, histological grading and the extent of local spread of the tumour, the 5-year survival rates following one or other type of operation were therefore compared for patients in whom the tumours showed similar pathological features.

Patients and methods

The records of all patients admitted to St Mark's Hospital with operable carcinoma of the rectum between 1963 and 1972 were examined. Patients were included in the study—provided they survived the first 28 days postoperatively—if the lower edge of the tumour on sigmoidoscopy was between 8 and 12 cm from the anal verge and if the operation was a radical procedure (i.e. a clinical decision was made at operation that all known growth had been removed). Patients treated by local excision of the tumour and those with ulcerative colitis or adenomatous polyposis were excluded. Patients who had had a second malignant tumour in the bowel or elsewhere either synchronously or metachronously and those in whom 5-year survival could not be established (10 patients) were also excluded. With these criteria, 199 patients were available for study—112 treated by total excision of the rectum and 87 by a restorative resection (including 6 in whom the anastomosis was carried out peranally).

A simple form suitable for computer analysis was designed recording clinical and pathological variables relating to sex, age, Dukes' classification, histological grading, extent of local spread, longitudinal measurement and outcome at 5 years. The cause of death was classified as due to carcinoma or unrelated cause; when the cause was unknown (14 patients) death was assumed to be due to carcinoma. (The patients shown as dead in *Tables III–VII* are those in whom death was due to carcinoma or unknown cause.) All results were analysed in the two groups. The significance of the contingency tables was assessed by the χ^2 test or by Fisher's exact test where appropriate and differences in age were assessed by Student's t test.

Results

Clinical attributes (Table I)

There was no significant difference in the sex distribution in the two groups but the mean age was significantly higher in the restorative resection group.

Pathological attributes (Table II)

The distribution of the Dukes' classification, histological grade and extent of local spread was significantly different between patients treated by total excision and those undergoing restorative resection. The mean longitudinal measurement of the tumour on the specimen was 5·0 cm in the former group and 4·8 cm in the latter. These figures were not significantly different.

Survival

The overall 5-year survival in the two groups is shown in *Table III*. A significantly higher proportion of patients treated by restorative resection survived 5 years. The women particularly showed this outcome, in the men it was less marked.

	Dead	Alive	Total
Total excision	10	6	16
Restorative resection	1	8	9

$P<0{\cdot}05$, Fisher's exact test.

Single variables: When *Dukes' classification* was studied there was no difference in survival for the Dukes' A (total excision 10/11, restorative resection 15/16) or B cases (total excision 31/42, restorative resection 27/38). For C cases, a significantly higher proportion of those treated by restorative resection were alive at 5 years; 17 out of 27 treated by restorative resection survived compared with 19 out of 53 treated by total excision ($\chi^2 = 4{\cdot}27$, $P<0{\cdot}05$).

There was no significant difference in survival between patients treated by either type of operation for any *grade of histology*; in particular survival rates were similar for patients with average grade tumours (total excision 37 out of 61, restorative resection 41 out of 56).

Survival was similar for total excision and restorative resection for patients with each of the *extents of spread*.

Two variables: Sufficient numbers of patients with Dukes' B tumours of average grade and Dukes' C of average grade were available for analysis. The 5-year survival in each of these categories was not significantly different for total excision or restorative resection (*Table IV*).

It was necessary to group the categories of spread to obtain sufficient numbers. Of all the analyses carried out involving Dukes' classification and spread, or histology and spread, the only group that showed a significant difference in survival between total excision and restorative resection was Dukes' B with slight or moderate spread. Survival was significantly better in the restorative resection group; 28 out of 34 survived compared with 24 out of 41 treated by total excision ($\chi^2 = 3{\cdot}9$, $P<0{\cdot}05$).

Three variables: To define the subgroups more exactly it was important to include all three variables to detect differences in survival. This resulted in small subgroups. There were significant differences in survival in some of the combinations. *Tables V, VI and VII* show that in selected groups patients treated by restorative resection fared better than those treated by total excision; in no instance was the reverse true.

Discussion

It is technically feasible to perform a restorative operation for some growths only a few centimetres above the anorectal ring, either by some form of pull-through procedure (Babcock, 1939; Bacon, 1956; Cutait and Figliolini, 1961; Turnbull and Cuthbertson, 1961) or by peranal anastomosis (Parks, 1972). These techniques, together with anterior resection, enable most rectal tumours to be treated by restorative procedures. It is essential to compare survival in these patients with those treated by excision. Prognosis depends largely on the pathological nature of the tumour. When attempting to compare the results of the two types of treatment the pathological features must be taken into account.

It has been maintained that the 5-year survival rate after restorative operations for carcinoma of the mid or upper rectum is similar to that obtained by complete rectal excision (Waugh et al., 1955; Palumbo and Sharpe, 1968). In these reports, however, there was no clear definition of the Dukes' stage, histological grade or extent of local spread of the tumours. It is quite possible that the more advanced and poorly differentiated tumours tend to be treated by total excision and the less advanced by restorative resection (Slanetz et al., 1972; Lockhart-Mummery et al., 1976). This bias is evident in the data presented in this study and, if not allowed for, would result in a possibly spurious advantage in favour of restorative resection. Attempts have been made to compare the results of these two operations for tumours of similar pathological stage. Slanetz et al. (1972) reported 5-year survival rates of 27 per cent and 22 per cent for abdominoperineal excision and anterior resection respectively in men with Dukes' C carcinoma between 8 and 18 cm from the anal verge. The corresponding figures for women were 52 per cent and 53 per cent. This analysis did not take the histological grade or the extent of local spread into consideration and the range of distances from the anal verge was too great for conclusions to be drawn about mid-rectal lesions. Glenn and McSherry (1966) determined the 5-year survival rates for patients with radically treated carcinoma of the rectum of Dukes' A, B and C stages lying above 10 cm from the anal margin. There was no statistical difference in survival after either anterior resection or rectal excision for tumours of the same Dukes' stage. Although other pathological features were not taken into account, this would suggest that the two operations produce similar results for tumours in the upper rectum.

In this study three different pathological features which influence prognosis were considered in comparing the results of excisional and restorative operations for carcinoma of the mid rectum. Ideally all the features should be combined, but this results in small numbers available for analysis. *Tables V*, *VI* and *VII* show that in certain subgroups patients with restorative resection fared better than those with total excision and in no case was the reverse true; however, it would be unwise to draw conclusions from such small numbers.

Comparison of survival in the two groups using only single variables may well lead to false conclusions. This is shown by the better survival of patients with Dukes' C tumours treated by restorative resection. This difference is very likely to be due to the greater proportion of high grade tumours in the Dukes' stage C total excision group (38·2 per cent compared with 17·9 per cent).

About 36 per cent of all operable rectal tumours are Dukes' B cases and Dukes' C cases form about 50 per cent, while almost 60 per cent are of average grade (Lockhart-Mummery et al., 1976). The two-variable analysis using these attributes is therefore the most useful for clinical practice. For tumours of average grade, no significant difference in survival following total excision or restorative resection for either Dukes' B or C tumours has been shown.

It is not possible to comment from this study on survival after removal of high grade tumours since there were only 5 patients with such tumours in the resection group. This reflects the attitude of surgeons who regard a preoperative biopsy showing a high grade tumour as an indication for total excision.

We conclude that for the most commonly occurring tumours in the mid rectum, i.e. Dukes' stage B or C tumours of average grade, the 5-year survival is similar after either total excision or restorative resection.

The results of vaginoplasty in excision of the rectum

GEORGE W. JOHNSTON*

SUMMARY

Vaginoplasty was used in a consecutive series of 45 patients undergoing rectal excision for neoplastic and inflammatory bowel disease. Forty-three patients achieved primary perineal healing and none developed a persistent perineal fistula.

One patient with Crohn's disease developed a perianal fistula a year after operation but healing occurred after minor surgery. Another developed a pre-sacral abscess 9 years after operation; spontaneous discharge into the vagina occurred.

MODERN colostomy and ileostomy appliances, coupled with the expertise of the stoma care nurse and the advice of self-help associations, have combined to reduce the problem of the artificial anus. Success in this area has focused more attention on the unsolved problem of the persistent perineal sinus. Ten years ago we described the operation of vaginoplasty as a method of obtaining primary perineal healing following rectal excision in the female (Johnston, 1969) and this paper reports the results of 10 years' experience with the method.

Operative technique

The rectum is excised without excision of the coccyx; the posterior vaginal wall is left intact initially. In inflammatory disease any fistulous or sinus tracts require to be laid open. The posterior vaginal wall is divided in the midline from the introitus to the cervix and transverse cuts are then made at the posterior aspect of the cervix freeing rotational flaps. Bleeding from the vaginal wall is easily controlled by diathermy but a running suture is more effective for the cervical margin. The lateral flaps of vaginal wall are now sutured to the side walls of the cavity with interrupted catgut sutures. The posterior fibro-fatty tissue is approximated with interrupted catgut sutures, building up the basis for the new posterior vaginal wall, and finally the skin wound is completely closed right up to the introitus. No perineal drainage tubes are necessary, the pelvic space draining freely through the newly constructed vagina. Actually the rotational flap grafts cover much of the raw cavity left by excision of the rectum, thereby reducing the volume of exudation and drainage.

Postoperatively the external dressing is changed as often as is required for the first couple of days and then daily irrigation of the vagina with eusol or saline is commenced. Sutures can be removed in 7–10 days, by which time the patient should be ready for daily baths. Over the next few weeks vaginal epithelium covers the small raw area on the newly constructed posterior vaginal wall. The patient may be allowed home 2 or 3 weeks after surgery with instructions to take daily baths and to wear merely a sanitary pad until any remaining discharge ceases; there is no need for the services of a district nurse. At the follow-up clinic a few months later the posterior vaginal wall is usually completely re-epithelized and the anterior perineum is virtually indistinguishable from normal.

Results

Obviously vaginoplasty is applicable only in the female patient, but it has been employed whether the rectal excision was required for cancer of the rectum or inflammatory disease of the large bowel. However, when a neoplasm involved the anterior rectal wall adjacent to the vagina, we routinely excised the whole of the posterior vaginal wall with the specimen thereby preventing the possibility of vaginoplasty; this group of patients was therefore excluded. This left a small personal consecutive series of 45 women treated by vaginoplasty at the time of rectal excision in the 10-year period under review. No patient was excluded because of perianal fistula, perineal sepsis, operative contamination or excess bleeding. Thirty patients had rectal excision for cancer, 9 for Crohn's disease, 5 for ulcerative colitis and 1 for an extensive villous papilloma. The patients' ages ranged from 22 to 90 (average 68). There were no operative deaths in the series. Primary healing of the perineal skin wound occurred in 43 of the 45 patients. In 2 elderly patients, one with a hemiplegia, the perineal wounds broke down on removal of the sutures, but fortunately both healed completely with simple secondary suture. No patient developed a pelvic or perineal abscess and there was no incidence of persistent perineal sinus formation. Although some patients left hospital within 2 weeks of operation the average postoperative hospital stay was 24 days, which is satisfactory considering the high average age of the group.

Further perineal problems occurred in only 2 patients. Both achieved primary perineal healing in spite of multiple preoperative perineal fistulas of Crohn's origin. More than 1 year after surgery one patient developed septic perineal sinuses which tracked subcutaneously and eventually produced a small fistula between the vagina and the perineum. This was resolved by further minor surgery. The other patient developed a small painful pre-sacral abscess 9 years after surgery. The abscess spontaneously discharged into the vagina, relieving the patient's symptoms and allowing resumption of normal sexual intercourse.

Discussion

Primary closure of the perineal wound was pioneered by Crile and Robnett (1950), who reported 78 per cent primary healing in patients with rectal cancer. Few have been able to better their results in spite of advances in bowel preparation, antibiotic therapy, drainage methods etc. (*Table I*). In inflammatory bowel disease the results are more depressing: primary healing of the perineal wound can be anticipated in only about 40 per cent of patients (*Table II*). Indeed, over 40 per cent may still have persistent perineal sinuses 6 months after surgery (*Table II*). About one-quarter of patients remain unhealed after 1 year and the majority of these are subjected to further surgery, although often little is accomplished by secondary operations.

It is generally agreed that the two major factors leading to perineal wound infection and subsequent sinus formation are operative contamination and inadequate drainage of the pelvic space. Frequently, in inflammatory bowel disease, pre-existing perineal sepsis makes operative contamination inevitable. In addition, the friable bowel is very susceptible to

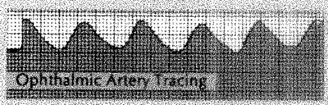
PULSE VOLUME RECORDER (PVR*)*

The NON-INVASIVE Clinical Vascular Laboratory

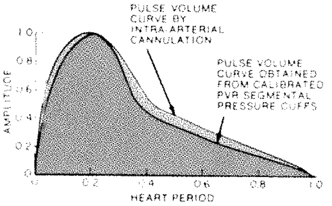
An Extensively Documented Clinical Procedure for the Quantitative Evaluation of Peripheral Vascular Disease:

Arterial – Venous – Cerebral

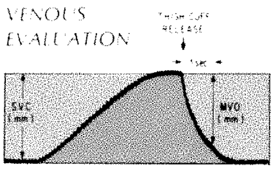
Excellent Long-term Reproducibility and Calibrated Accuracy by Quantitative Segmental Cuff Technique



Ophthalmic artery pressure is read directly on the OPG Attachment of the PVR for the evaluation of collateral circulation to each eye, and its respective cerebral hemisphere.



Comparison of pressure contours obtained with the PVR and direct cannulation of the common femoral artery.



A 15-point scale provides approximately 5% false (+) and 2% false (-).

Total Segmental Perfusion (primary vessel plus collaterals) is accurately documented at the thigh-calf-ankle-metatarsal level and digits. The built-in Doppler facilitates the measurement of pressures along the arterial tree.

The COMBINED information of segmental PVR recordings and systolic pressure gradient establishes a clinically accurate picture of functional perfusion.

Now available with built-in, Recording Bi-Directional Doppler

SHOCK

Trasylol®

aprotinin

increases the chances of survival in traumatic-haemorrhagic shock

The results of a large German field study[1]: Marked reduction of mortality when Trasylol was applied early. Precise clinical investigations in 70 shock patients by an Australian double-blind study[2] provided an explanation and further proof for the effectiveness of Trasylol in shock: With Trasylol development of post-traumatic respiratory insufficiency (shocklung) was less frequent.

Bayer

Composition
Polypeptide from bovine lung with inhibitory action on proteinases.

Dosage
Initially 500,000 KIU Trasylol slowly intravenously or by short term infusion (5 ml/min to the patient in the recumbent position), thereafter every 4 hours 200,000 KIU slowly i.v.

Precautions
Trasylol may in very rare cases (less than 0.1%) cause hypersensitivity reactions.

Presentation
Ampoules of 100,000 KIU (Kallikrein Inactivator Units)
Ampoules of 200,000 KIU *

damage, especially from traction by either the abdominal or perineal operator. The advantage of vaginoplasty is that such contamination does not preclude primary perineal suturing since the pelvis and perineum continue to drain freely through the newly constructed vagina. This prevents the formation of pelvic haematomas and thus minimizes the possibility of closed sepsis. Primary healing of the perineal wound is the rule rather than the exception.

In the past there has been a reluctance on the part of general surgeons to interfere with the vagina for fear of impairing vaginal function. However, Professor Goligher found that even after excision of the whole posterior vaginal wall in patients with rectal cancer the functional result was excellent (Goligher, 1967). By contrast, the operation of vaginoplasty sacrifices no vaginal tissue and amounts to little more than an episiotomy. In addition, the interference with muscle function of the organ differs little from that of routine rectal excision where the pelvic vaginal sphincter (the puborectalis muscle) is divided and the perineal vaginal sphincter (the bulbospongiosus muscle) rendered functionally useless by interference with the perineal body. In the present series, where vaginal function has been tested, both patients and husbands have reported no diminution in sexual satisfaction. In 1973 Hughes and Cuthbertson concluded 'there is no sure way of preventing the formation of a perineal sinus. It does not seem to be due to the manner in which the perineal wound is closed at operation.' Perhaps for the female, vaginoplasty provides the answer.

Fulminating amoebic colitis: a clinical evaluation

T. VAJRABUKKA, A. DHITAVAT, B. KICHANANTA, Y. SUKONTHAMAND,
C. TANPHIPHAT AND S. VONGVIRIYATHAM*

SUMMARY

Eleven cases of fulminating amoebic colitis seen in 5 years are reported. Only people of low socioeconomic status were affected and most were in good health previously. The disease appeared to follow a fulminant course from the onset and was rarely a secondary phenomenon superimposing on the chronic amoebic dysentery. The diagnosis was difficult due to severe systemic manifestations and the periodic absence of Entamoeba histolytica in the stool. The development of colonic necrosis was often masked by the severe pre-existing local signs and perforation could occur in spite of adequate anti-amoebic therapy. Mortality was related to late diagnosis, delayed recognition of irreversible colonic necrosis and inadequate surgical treatment.

To reduce the present 55 per cent mortality further it is proposed that, in an endemic area, early specific anti-amoebic therapy is justified in severe and undiagnosed colitis. Even under specific anti-amoebic treatment the patient with severe amoebic colitis remains a potential surgical candidate. Surgery is indicated when the patient continues to deteriorate in spite of the therapy, when there is an acute episode which signifies perforation, or when severe diarrhoea, toxaemia and abdominal tenderness persist after a full course of specific anti-amoebic therapy. Primary total resection of the diseased colon is the treatment of choice.

AMOEBIASIS is endemic in Thailand and amoebic colitis is normally a mild disease which responds well to medical treatment. Fulminating or necrotizing amoebic colitis is an unusual form of amoebic colitis characterized by severe toxaemia, rapid and extensive colonic necrosis and multiple perforations. Because of its rarity the disease is not generally recognized before irreversible colonic necrosis occurs and is almost invariably fatal. It is the purpose of this paper to present our experience in the diagnosis and management and to show that when surgical intervention is timely and adequate the prognosis of this once grave condition is vastly improved.

Patients and methods

From 1974 to 1978 inclusive 11 patients with fulminating amoebic colitis were treated in the surgical department, Chulalongkorn Hospital, Bangkok. The amoebic nature of the colitis was confirmed by the demonstration of *Entamoeba histolytica* in the stools or in the resected colonic tissues in 10 patients and by a positive specific serological test in one patient. In those who presented with diarrhoea laboratory tests included stool examination and culture, serological tests for enteric fever and blood culture. All 11 patients underwent exploratory laparotomy and received intensive postoperative supportive treatment including parenteral antibiotics (penicillin or chloramphenicol with gentamicin or kanamycin), fluid and electrolyte replacement and blood transfusion when indicated. When the diagnosis of amoebiasis was made the patients were given either dehydroemetine or metronidazole or both.

Results

The clinical features are shown in *Table I*. The patients in this series belonged to the low socioeconomic groups. One patient (*Case* 10) had a previous history of treated amoebic dysentery and remained asymptomatic until the present attack. All except 2 patients appeared to be in good health previously. Of the 2 debilitated patients one was a young heroin addict who contracted the disease while in prison (*Case* 4). This patient had had diarrhoea for 4 months and may have been malnourished before the colitis. The other ill patient (*Case* 11) was an elderly man with congestive cardiac failure.

In all but *Case* 4, already referred to, there was only a short history of diarrhoea, varying from 2 days to 3 weeks. In one patient (*Case* 3), whose disease was confined to the right colon, there was no history of diarrhoea. The onset of diarrhoea was usually abrupt with 5–15 stools per day and was associated with toxaemia and abdominal tenderness. In some patients (*Cases* 6 and 7) the diarrhoea was watery and explosive initially, simulating acute bacillary dysentery. Many patients (*Cases* 1, 2, 6, 7 and 9) denied the presence of blood in the stools but red and white blood cells were often found on microscopic examination. In most cases mucus was present and mixed with a small amount of loose stool with each bowel action. As the disease progressed the toxaemia and the frequency of the diarrhoea increased. Eventually the diarrhoea consisted of continuous passage of copious white glairy mucus exudate mixed with occasional necrotic casts of mucosa.

In spite of very severe colitis, amoebae could not be demonstrated on initial microscopic examinations of the stools in 7 of 8 patients. Subsequent stool examinations revealed numerous amoebae in 2 of these 7 patients. Hence preoperative confirmation of amoebic colitis was possible on the basis of stool examination in 3 patients only (*Cases* 1, 4 and 5); in only 2 (*Cases* 4 and 5) was there sufficient time to commence anti-amoebic treatment. One patient (*Case* 11) received preoperative anti-amoebic therapy for suspected giardiasis.

The progress to colonic gangrene and peritonitis was rapid, varying from 4 days to 3 weeks in most patients and after a chronic course of 4 months in only 1 patient (*Case* 4). In most patients there was no dramatic turning point to indicate the onset of gangrene of the colon. The clinical picture was that of gradual deterioration as indicated by the worsening of toxaemia, abdominal distension, tenderness and diarrhoea. Only when peritonitis had become fully established was gangrene of the colon with rupture recognized. A delay in recognition of colonic gangrene of up to 2 days occurred in 8 patients, up to 3 days in 2 patients (*Cases* 4 and 6) and 4 days in 1 patient (*Case* 11).

Operative findings and management

The inflamed and extremely friable colon was usually found wrapped in omentum and adherent to the

Adm., admission; op., operation; *E. hist.*, *Entamoeba histolytica*; surv., survived.

inflamed parietal peritoneum. There were areas of full-thickness colliquative necrosis and areas with relatively normal serosa concealing complete mucosal necrosis. Perforations were usually multiple and widely distributed. Many perforations were partially concealed in the inflamed omental envelope and became evident as soon as the colon was touched. In more severe cases long necrotic segments of the colon had completely disintegrated with free spillage of content. The extent of colonic involvement was as shown in *Table I*. Conservative surgery, i.e. drainage with external faecal diversion or internal bypass, was performed in 3 patients (*Cases* 2, 6 and 9) with disastrous consequences. It resulted in rapid deterioration due to spreading colonic necrosis in spite of specific anti-amoebic treatment. One of these patients (*Case* 2) died within 4 days of the operation from severe toxaemia, 2 patients required re-exploration because of peritonitis and only 1 patient (*Case* 9) survived after a colonic resection. Conservative surgery was used as a temporary procedure in 1 patient (*Case* 11) in the hope that the patient might improve sufficiently to allow colonic resection later. There was no improvement and the patient died after colectomy.

Resection of the diseased colon with external faecal diversion and abdominal drainage was performed in 7 patients and 4 survived.

Mortality

Six patients in this series died, giving an overall mortality of 55 per cent. Early postoperative deaths were due to shock and toxaemia while late deaths were due to sepsis. The mortality rate was 75 per cent among those who had conservative surgery such as diversion and drainage as the primary procedure and 43 per cent for those who had resection with exteriorization as the primary procedure. The mortality was related to the extent of colonic necrosis. When the disease was confined to the area proximal to the mid-transverse colon the mortality was 33 per cent compared with 57 per cent with more distal colonic involvement and 100 per cent with entire colorectal involvement. Mortality was also related to the preoperative condition of the patients. Among those with a poor preoperative state, as characterized by persistent shock (systolic blood pressure below 100 mmHg), associated cardiopulmonary insufficiency, electrolyte imbalance and hypoproteinaemia with generalized oedema, the mortality was 80 per cent compared with 33 per cent in those in a better preoperative condition. Delay of more than 48 h in the diagnosis of colonic necrosis and peritonitis also resulted in a mortality of 67 per cent, twice as high as in those with an earlier diagnosis (38 per cent).

Discussion

Fulminating amoebic colitis has been observed in debilitated subjects who are suffering from malnutrition, chronic illnesses and intestinal infections (Adams and Maegraith, 1960). In an area where amoebiasis is endemic, infestation with various intestinal parasites is also rife. The role of these parasites in the pathogenesis of fulminating amoebic colitis is not known. Their association in many of our cases, together with the low socioeconomic background of the patients, is indicative of the poor hygiene and low standard of health of these people. Similar predisposing factors have been observed by others (Palaez et al., 1966).

The diagnosis of amoebic colitis normally rests on the typical history of bloody mucous diarrhoea, proctoscopic or sigmoidoscopic observation of typical amoebic ulcers and, particularly, the demonstration of *E. histolytica* in the stools and mucus. In fulminating amoebic colitis the diagnosis is difficult because of its unusual presentation. The disease runs a fulminating course in most patients, with diarrhoea of varying severity. The diagnosis on clinical history is relatively easy only in the rare event of the disease superimposing upon the chronic form of amoebic colitis. Sigmoidoscopy is difficult because of the almost continuous passage of mucus and because the friability of the colon makes it hazardous. When performed gently and skilfully without air insufflation, sigmoidoscopy may provide a diagnosis in a limited number of patients with rectal or sigmoid involvement. The curious periodic absence of amoebae in the stools further compounds the diagnostic difficulty and much valuable time is lost in pursuing alternative diagnoses such as bacillary dysentery, typhoid or even idiopathic ulcerative colitis, which is very rare in Thailand. By the time amoebiasis is confirmed it is often too late to commence effective anti-amoebic therapy. We feel that in an area where amoebiasis is endemic a trial of anti-amoebic therapy is worth while in patients with severe, undiagnosed colitis. In such instances the diagnosis must depend first upon the therapeutic response and later on the result of specific serological tests. Prompt anti-amoebic therapy may arrest the progress towards irreversible colonic necrosis in some patients and in others may improve the prognosis should surgery become necessary. The cardiac toxicity of emetine makes it unsuitable in many patients who are already hypotensive from toxaemia; metronidazole is much safer and equally effective.

The detection of colonic necrosis without perforation is difficult in fulminating amoebic colitis because its development is insidious and is usually masked by severe pre-existing local signs and toxaemia. Mucous diarrhoea often continues in the presence of colonic necrosis and peritonitis. By the time perforation is recognized from the X-ray evidence of free air under the diaphragm the patients are usually very ill from toxaemia, making operation hazardous. Clearly every effort must be made to detect the stage of irreversible colonic necrosis and to operate before the patient's condition becomes precarious. This requires an awareness of the diagnosis and vigilant monitoring of the vital signs, abdominal girth, tenderness, severity of diarrhoea and frequent abdominal X-rays to detect dilated featureless colon (toxic megacolon). False optimism on the confirmation of the amoebic nature of the colitis must be resisted. Severe amoebic colitis may require operation at any stage and anti-amoebic drugs cannot prevent a necrotic colon from sloughing even if all amoebae have been eradicated (Stein and Bank, 1970; Mukerjee and Nigam, 1975). We agree with Stein and Bank (1970) that persistent diarrhoea, abdominal tenderness and severe toxaemia, despite adequate anti-amoebic therapy, are indicative of severe colonic necrosis and the need for operation.

Our results suggest that there is no place for conservative surgery, particularly in undiagnosed or untreated patients. It has long been known that diversion, or diversion alone, seems to accentuate the sloughing of the necrotic colon (Manson-Bahr, 1939). The best operative treatment is primary resection of the diseased bowel with exteriorization of the ends in all patients who are fit for laparotomy.

In the past fulminating amoebic colitis always carried a mortality approaching 100 per cent, whatever the form of operative treatment (Hawe, 1945; Rives et al., 1955; Palaez et al., 1966; Chen et al., 1971; Sharma et al., 1975). This was due to the poor preoperative state as a result of delay or inadequate surgical treatment or both. The overall mortality in this series is 55 per cent and indicates that fulminating amoebic colitis is not inevitably fatal. It is our contention that we can reduce the mortality further by employing a high degree of suspicion, prompt anti-amoebic therapy, careful clinical evaluation and, if there is not rapid improvement, adequate resectional surgery.

Bleeding duodenal ulcer: reduction in mortality with a planned approach

P. S. HUNT, M. G. KORMAN, J. HANSKY, R. D. MARSHALL,
G. S. PECK AND W. J. MCCANN*

SUMMARY

In a 6-year prospective study from 1972 to 1978 266 patients were admitted to a haematemesis and melaena unit with bleeding duodenal ulcer. There were 13 deaths, a mortality of 5 per cent. A comparison between the three consecutive 2-year periods of study showed an initial mortality of 6 per cent for the first 4 years falling to 2 per cent for the 93 admissions during the final 2 years of experience. Of the 120 patients treated surgically, 10 died in hospital, giving an operative mortality of 8 per cent. The trend in operative mortality was from 13 per cent for the initial 2-year period to 8 per cent for the second period and to 3 per cent for the final 2 years. The operative rate was consecutively 45, 50 and 34 per cent. There was 1 death in conservatively treated patients during each 2-year period of study. Three types of operation were performed: vagotomy, pyloroplasty and oversewing of the ulcer; Polya gastrectomy; and vagotomy and antrectomy. There was no difference in morbidity and mortality between these operations. At a mean follow-up of 3·1 years, 90 per cent of the patients had a good result from their operation. It is concluded that a prospective system of management with an active policy of early endoscopy, surgery and regular audit reduces the mortality from bleeding duodenal ulcer.

BLEEDING chronic duodenal ulcer is the commonest cause of haematemesis and melaena. Retrospective studies have shown that this disease accounts for more than 30 per cent of admissions with upper gastrointestinal haemorrhage and that bleeding duodenal ulcer is a significant cause of death in hospital practice, with a mortality of 5–7 per cent (Schiller et al., 1970; Hardy, 1974). In addition, Schiller et al. (1970) showed that over a 15-year period their mortality rate remained constant. These authors noted an emergency operative rate of 29 per cent, and concluded that to improve results emergency surgery should be performed more frequently and that vagotomy with drainage is the operation of choice.

At our hospital retrospective analysis of the period from 1951 to 1970 showed an unacceptably high mortality of about 12 per cent for bleeding duodenal ulcer. This finding prompted the establishment of a haematemesis and melaena unit in 1972. Patients were managed according to a defined protocol depending on the cause of bleeding. All patients presenting to the hospital with this problem were admitted to the unit. Thus, this unit managed the complete sample of patients with bleeding duodenal ulcer presenting from an Australian urban setting. Prospective analysis of these patients is reported in an attempt to study whether such a unit influences the outcome of patients with bleeding chronic duodenal ulcer.

Patients and methods

There were 894 admissions to the unit over the 6 years of prospective study from 1972 to 1978. The total number of admissions due to bleeding duodenal ulcer was 282. All patients were admitted to a designated area of the hospital under the care of a gastroenterologist, surgeon and gastroenterology registrar. The policy of management specified immediate resuscitation and endoscopy within 12 h of admission. The indication for blood transfusion was shock and/or a haemoglobin of less than 10 g/dl. Patients were endoscoped with the forward-viewing Olympus or ACMI instruments. During the first year of the study all patients had a subsequent barium meal examination, but later this was only performed in those patients unsuitable for endoscopy or where the diagnosis remained in doubt.

In chronic duodenal ulcer an active policy of surgical management was pursued. This approach was substantiated by a review of results at 3 years (Sereda et al., 1977) which confirmed that patients over 50 years of age and shocked were the most likely to die. Surgery was performed in such patients after resuscitation, and in those with recurrent or continued bleeding requiring more than 5 units of blood. Four surgeons were involved and the policy of the unit was for those surgeons to perform their preferred operation. The operations performed were Polya partial gastrectomy, truncal vagotomy, pyloroplasty and oversewing of the ulcer and truncal vagotomy and antrectomy with a Polya anastomosis.

Exhibition of the protocol and 6 monthly reports within the hospital were considered an important part of the method. Every patient admitted was discussed at weekly gastroenterology meetings.

Results

Overall results

There were 282 admissions to the unit with bleeding duodenal ulcer. This group comprised 266 patients (156 females and 110 males) of a mean age (± s.d.) of 54·4 ± 17 years. Sixteen patients were admitted on two occasions (89 per cent). Emergency surgery was performed on 120 patients (43 per cent), whilst for 162 admissions conservative treatment was followed. Of the 16 patients readmitted on a second occasion, 6 underwent emergency surgery whilst 10 were again treated conservatively, either because of associated disease (cancer, severe cardiac or respiratory disease) or because they refused surgery (*Table I*).

There were 13 deaths during the 6-year period (4·5 per cent). Ten occurred in patients who underwent emergency surgery whilst 3 patients died (1 following endoscopic perforation) in the group that was treated medically. The haemodynamic data from these patients revealed that 121 (43 per cent) received more than 5 units of blood, 164 (58 per cent) had a haemoglobin of 10 g/dl or less on admission and 85 (30 per cent) were shocked on admission (*Table II*).

There were associated lesions in the upper gastrointestinal tract of 54 patients at endoscopy. These were not the source of major bleeding. This included 15 patients with acute gastric ulceration; 4 with small

varices; 6 with chronic benign gastric ulcer; 5 with Mallory–Weiss tear; 14 with oesophagitis; 9 with hiatus hernia; and in 1 patient there was also a pyloric channel ulcer.

Trend in clinical experience

In order to evaluate trends, comparison was made between the three consecutive 2-year periods of study (*Table III*). During 1972–4 there were 88 admissions with duodenal ulcer and 6 deaths (7 per cent); 1974–6, 101 admissions and 5 deaths (5 per cent); 1976–8, 93 admissions and 2 deaths (2 per cent). The operative mortality was 5 of 40 operations (13 per cent) for the first 2 years, 4 of 50 operations (8 per cent) for the second 2-year period and 1 of 32 operations (3 per cent) for 1976–8. The operative rate has varied from 45 per cent to 50 per cent to 34 per cent in each 2-year period. In the medically treated patients there was 1 death in each 2-year period. There was no change in the incidence of shock on admission. The endoscopic diagnostic rate rose from 73 per cent in 1972–4 to 97 per cent for 1974–6 to 98 per cent for 1976–8.

Results of medical management and follow-up

A total of 152 patients was admitted and treated medically, 16 of these were readmitted and 10 were again treated conservatively (*Table IV*). Thus, for 162 admissions medical treatment was followed. The mean (± s.d.) age of this group of patients was 54 ± 17 years. In 53 of these patients (34 per cent) there was a past history of upper gastrointestinal bleeding.

Three patients died in hospital. Follow-up has revealed that a further 21 patients have died from 3 months to 5 years after admission. The cause of death was from diseases unrelated to duodenal ulcer, except in one patient who died from massive gastrointestinal bleeding at another hospital. There were 16 patients lost to follow-up, giving a follow-up rate of 89 per cent for a mean period of 2·9 years. Twenty-five patients subsequently underwent elective surgery for duodenal ulcer, usually for symptoms not controlled by medical management.

Results of surgical management and follow-up

One hundred and twenty patients were treated by emergency operation (43 per cent) (*Table V*). Six of these patients had previously been admitted to the unit. The mean (± s.d.) age of these patients was 57 ± 15 years. There were 10 deaths, giving an operative mortality of 8 per cent. Three varieties of procedure were performed with no difference in mortality for each procedure. Six patients died more than 3 months after discharge; 4 deaths were due to diseases unrelated to duodenal ulcer and in 2 cases the cause of death was unknown. Seven patients were lost to follow-up giving a follow-up rate of 94 per cent.

These patients were followed for a mean of 3·1 years and clinical results were assessed according to Visick criteria as modified by Goligher et al. (1978). Of the 45 patients treated by Polya gastrectomy 39 were Visick grade I or II (81 per cent). There were two proved recurrent ulcers in this group. Of the 37 patients followed up after truncal vagotomy and pyloroplasty 33 were Visick grade I or II (75 per cent), and there was 1 proved recurrent ulcer. All 17 patients followed up after truncal vagotomy and antrectomy were Visick grade I or II at completion of this follow-up study.

Discussion

In this prospective study the overall mortality was 5 per cent, which compares favourably with available complete retrospective reports from Britain (Schiller et al., 1970) and North America (Himal et al., 1974). Most studies have the disadvantage of being retrospective and of taking only an incomplete sample of patients presenting to individual hospitals. This

Fogarty®
Biliary Balloon Probe

one of the famous family of Fogarty catheters

- simple removal of intrahepatic calculi without routine duodenotomy
- reduction of incidence of retained stones following common duct surgery*

prospective study suggests that with a planned approach to the problem, mortality can be reduced and supports the concept of early endoscopy and an active surgical approach. Early surgery, particularly in patients over 50 years of age, is supported by the experience of Jones et al. (1973) in Aberdeen, who noted a significant relationship between mortality and further haemorrhage in hospital in patients of over 60 years of age or with coincidental disease.

During the three 2-year periods the mortality trend was from an initial mortality of 6 per cent during the first 4 years to 2 per cent in the final 2 years. During the last year of the study there were no deaths in 45 admissions, 16 of whom underwent surgery. In a retrospective study at Prince Henry's Hospital, the surgical mortality for bleeding duodenal ulcer was 24 per cent for 1951–60 and 17 per cent for 1961–70 (Hunt et al., 1978). Before the unit was established patients were usually managed in medical units, diagnosis was not made early and surgical consultation was often late. Correction of these factors by admission to a specialist unit, early endoscopic diagnosis and a combined medical/surgical approach has possibly been responsible for the decreased mortality. There must be an occasional patient with advanced disease (cancer, cardiac or respiratory disease) or extreme age in whom no treatment is desirable. This accounted for 2 of 3 deaths in the medically treated group. The natural history of the medically treated patient is of interest. In 35 per cent there was a past history of upper gastrointestinal bleeding. This supports the contention of Hallenbeck (1970) that recurrent bleeding is common.

The surgical mortality was 8 per cent. This compares favourably with the best retrospective results from Britain and North America (Schiller et al., 1970; Himal et al., 1974), these series reporting mortalities of 7–9 per cent for urgent surgery in bleeding duodenal ulcer. The surgical mortality at Prince Henry's Hospital showed an initial mortality of 13 per cent during the first 2 years falling to 8 per cent for the second 2 years to a final 2-year surgical mortality of 3 per cent. The latter result compares with the best result of 2 per cent reported from Sydney (Bambach et al., 1976). A prospective study from Montreal (Himal et al., 1978) has also shown a fall in mortality for bleeding duodenal ulcer to 2 per cent.

The reduced mortality associated with the more conservative operation (Carruthers et al., 1967; Schiller et al., 1970), i.e. vagotomy and pyloroplasty, was not seen in this study—the three operations having an operation mortality of 5–8·5 per cent. While individual surgeons in the unit had a preference for a particular operation, in practice, each surgeon performed a variety of operations depending upon the circumstances. Partial gastrectomy of the Polya type was performed when vagotomy might have been difficult, such as when varices were present, or when there was marked obesity or an enlarged left lobe of the liver. Also, some surgeons chose partial gastrectomy instead of pyloroplasty when there were very large circumferential oedematous duodenal ulcers. Thus, partial gastrectomy was performed in some poor risk patients though there is little doubt that vagotomy, pyloroplasty and oversewing is the most effective, expeditious operation to be generally recommended, especially in the aged. Rebleeding was uncommon and rarely severe. In only one case having undergone vagotomy and pyloroplasty was reoperation necessary for rebleeding. This was early in the series and it is clear that careful oversewing of the ulcer with non-absorbable sutures is essential to prevent this complication. Follow-up of patients though incomplete (94 per cent) and early (mean, 3 years) suggests that sequelae were uncommon, which is in agreement with the results of Goligher et al. (1978).

Anti-Xa factor as a predictor of postoperative deep vein thrombosis in general surgery

IAIN G. GUNN*

SUMMARY
This study was stimulated by a recent report linking a low preoperative level of an endogenous coagulation inhibitor (anti-Xa factor) with an increased incidence of postoperative deep venous thrombosis (DVT) (Stamatakis et al., 1977).

Preoperative and postoperative levels of anti-Xa were measured and correlated with the postoperative incidence of deep venous thrombosis assessed by the ^{125}I fibrinogen uptake test to determine whether a high risk group could be isolated and a suitable regimen of prophylaxis introduced.

In this study of 22 surgical patients the postoperative DVT rate was 41 per cent. However, preoperative measurements of anti-Xa activity failed to show any statistically significant difference between those patients with DVT and the non-DVT group. The findings do not support the use of anti-Xa levels as a preoperative predictor of postoperative DVT in the individual.

ANTI-XA factor is thought to be important in the pathogenesis of DVT as an endogenous, homeostatic neutralizer of factor Xa which itself generates relatively large quantities of thrombin from thromboplastin. Thus a patient with a low preoperative level of anti-Xa activity may be unable to maintain equilibrium in the face of considerable quantities of factor Xa generated by surgical trauma. This would result in a hypercoaguable state producing an increased incidence of postoperative DVT. This study aimed to assess this connection between anti-Xa levels and the occurrence of DVT.

Patients and methods

A total of 22 patients from the general surgical wards of the Southern General Hospital, Glasgow, were studied. All these patients underwent elective procedures involving either laparotomy or thoracotomy. Their mean age was 58 years, with a range of 34 to 80 years. No special prophylactic measures other than early ambulation were taken to prevent postoperative thrombosis.

Plasma samples for anti-Xa estimations were drawn by venepuncture at least 12 h preoperatively. Further samples were taken during the operative procedure and 24 h postoperatively. Anti-Xa levels were assessed by the technique of Yin and Wessler (1970) which is specific in estimating the anti-Xa activity of plasma.

Assessment of patients for postoperative DVT employed the ^{125}I fibrinogen uptake test, the accuracy of which has already been established (Flanc et al., 1968; Kakkar and Flanc, 1968). One hundred μCi of ^{125}I fibrinogen were administered intravenously immediately after the preoperative anti-Xa sample had been withdrawn. Two hours later preoperative reference scans of both legs in seven positions from the ankle to the level of the adductor canal were performed. Diagnostic scans were carried out on postoperative days 1, 3, 5, 7 and 9 with daily scans of any leg showing significantly increased uptakes.

Using this technique 9 out of the 22 patients (41 per cent) were considered to have developed DVT and the preoperative anti-Xa levels of these patients and of the non-DVT group are shown (*Fig.* 1).

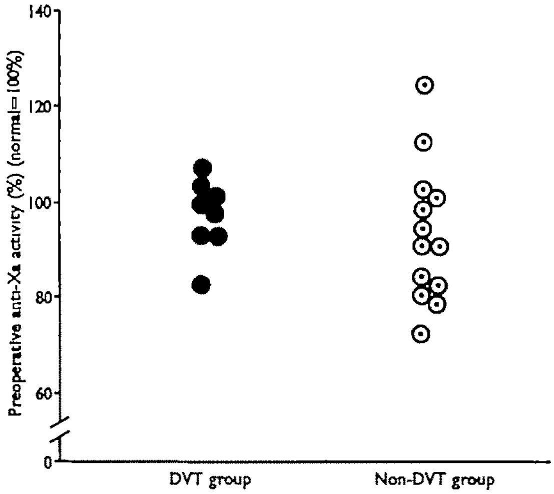

Fig. 1. Preoperative anti-Xa levels in 22 patients.

Conclusion

In this study no correlation is evident between preoperative low anti-Xa levels and postoperative DVT: in fact, the mean preoperative anti-Xa levels are higher (99 per cent) in the DVT group than in the non-DVT group (96 per cent). Six patients had a low preoperative anti-Xa level of less than 90 per cent but only one of these developed postoperative thrombosis. Similarly, the anti-Xa levels estimated intra- and postoperatively failed to show any statistically significant differences between the DVT and non-DVT groups.

Although anti-Xa may yet prove to be an important factor in our understanding of postoperative DVT, this study indicates that a preoperative assessment of the activity of this coagulation inhibitor cannot accurately predict the risk of postoperative DVT in an individual patient and thus is not a useful measurement on which to base anti-thrombosis prophylaxis.

The fibrinolytic activity of the vein following venous stasis

ANDREW V. O. WU AND AVERIL MANSFIELD*

SUMMARY

This animal study investigated the fibrinolytic activity in the vein wall of the pig following venous stasis, which was induced artificially using an intermittently inflated pneumatic cuff. The method used to measure the fibrinolytic activity was modified from Todd's original technique. The area of lysis and the area of the vein wall were measured and expressed as a ratio, called the fibrinolytic index. After 3 h of intermittent venous stasis the fibrinolytic index was reduced by 68 per cent, significantly lower than the control group.

The reduction of the fibrinolytic index by venous stasis could play an important part in the development of deep vein thrombosis.

PERMIN (1947) found that areas of lysis occurred when pieces of tissue were placed on a fibrin clot and incubated. Todd (1958) used a histochemical method to confirm and locate the presence of fibrinolytic activity in the vein wall. Pandolfi et al. (1968) modified this method by grading the areas of lysis and estimated the level of fibrinolytic activity in the veins of volunteers and patients.

We present here a quantitative method, also based on Todd's original technique, to measure the fibrinolytic activity in the vein wall following artificially induced venous stasis.

Materials and methods

Our experimental animal was the pig, each weighing 30–35 kg. Anaesthesia was induced and maintained with fluothane/nitrous oxide/oxygen and with endotracheal intubation.

We used 2 animals for the study of pressure and flow effect of the pneumatic cuff, which was 5 cm wide and was placed around the hind leg of the pig. In one animal the distal part of the femoral vein was exposed and through separate tributaries two fine 21 G plastic catheters were inserted into the deep vein. The tip of one was placed distal to the cuff and the other advanced to the iliac vein. After the catheters were secured the incision was closed and the catheters were connected to the pressure monitor via transducers. The pneumatic cuff was then inflated to a pressure of 225 mmHg for 10 min and this was repeated after 10 min release. Pressure changes in the vein on either side of the cuff were recorded simultaneously during stasis and during release. In the second animal venograms were performed through a peripheral vein to visualize the deep vessels during stasis. Following this the femoral vein was exposed in an attempt to measure the venous flow during stasis. This was unsuccessful. No data could be obtained because the easily collapsible vein made proper contact with the electromagnetic probe technically impossible.

We then studied two groups of pigs. In the stasis group each of the 5 animals had the leg cuff intermittently inflated to the same pressure as before for 20 min and then released for 10 min; the cycle was repeated for a total period of 3 h. In the control group of 5 animals no pneumatic cuff was applied but each animal was anaesthetized for 3 h. From each of these animals a series of biopsies was obtained from the saphenous vein, distal to the cuff, before and at 20, 90 and 180 min after the onset of stasis. Commencing distally, segments of the vein between two tributaries were successively removed at the set time so that the flow of blood in the more proximal part of the vein was maintained and remained in communication with the deep veins. Each vein sample, measuring 5–8 mm in length, was gently rinsed in buffered saline to remove the blood within its lumen. It was placed on a small block of supporting tissue (boiled liver) and was immediately frozen in isopentane cooled by carbon dioxide ice. The sample was then stored at −20 °C until used. Using the Cambridge Cryostat each vein sample was sectioned to a thickness of 10 μm. Each of the eight sections obtained from the same vein sample was placed on a 16-mm round glass coverslip which had been thoroughly cleaned to remove all traces of grease. To facilitate handling, four such coverslips were carried on one microscope slide. Using a Pasteur pipette, a thin film of topical thrombin, at a concentration of 20 units/ml, was applied over the vein section. Then, 0·05 ml of a mixture of fibrinogen, plasminogen and phosphate buffer (Pandolfi et al., 1968) was gently spread over the whole area of the coverslip. After 15 min in a moist chamber, at room temperature for the fibrin to consolidate, the plates were placed in a moist incubator at 37 °C. At the end of 1 h the plates were placed in a solution of 10 per cent buffered formalin for 10 min. The plates were then stained with Harris's haematoxylin and then Giemsa stain before being left at room temperature to dry.

On examination under the microscope the lytic areas were clearly seen to be related mainly to the adventitia of the vein. The total area of lysis was measured in mm² with the aid of a counting grid attached to the eyepiece. The area of the vein wall was measured by the product of the length of the intima and the mean thickness of the vein wall. The fibrinolytic index was calculated as a ratio in the following formula:

$$\text{fibrinolytic index} = \frac{\text{area of lysis mm}^2}{\text{area of vein wall mm}^2}.$$

The fibrinolytic index for the vein was the mean obtained from eight separate sections of that vein. In order to detect any contaminating activator substance, as controls, sections of boiled liver were processed in the same way at the same time.

Results

The venogram (*Fig*. 1) shows that there are two large deep veins draining the pig's hind leg, and when the cuff is inflated the more superficial femoral vein is occluded at the level of the cuff, but the other deep vein is only slightly narrowed with no interruption of flow. The pressure curve (*Fig*. 2) shows that when the cuff is inflated the distal venous pressure rises sharply but within 2 min it falls to normal and remains low until the cuff is released when there is another drop in pressure. The second and subsequent cycles show that the pressure spikes are even smaller than the initial one, indicating the presence of venous dilatation and a diversion of the blood flow to the alternative deep drainage system. In the iliac vein the pressure curve has an opposite and much lesser effect. These experiments suggest that the thick fleshy hind quarter of the pig protects the deep veins from complete occlusion by the cuff. There is stasis because the peripheral veins are dilated (*Fig*. 1) but venous hypertension is absent. The range of pressure applied to the cuff to produce the desired stasis effect is wide. It is almost impossible to produce complete vascular occlusion with this method.

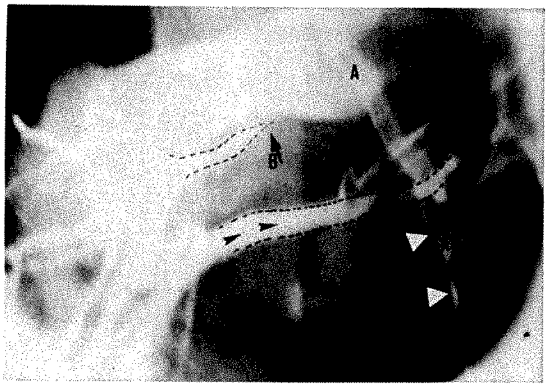

Fig. 1. Venogram taken with the cuff inflated. Arrows point to the direction of blood flow. A, level of cuff; B, occluded superficial femoral vein; C, deep vein slightly narrowed but patent.

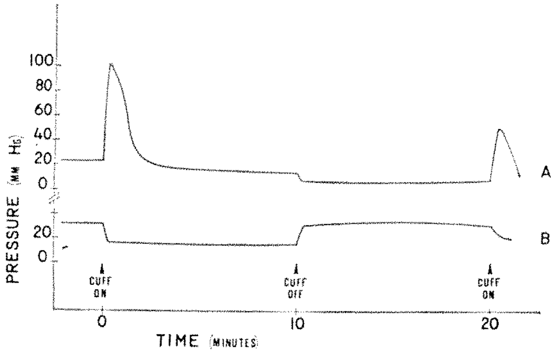

Fig. 2. Time/pressure curve recorded simultaneously from two catheters inserted into the superficial femoral vein. A, pressure distal to the cuff, no persistent venous hypertension; B, pressure proximal to the cuff.

In the control group of animals (*Table I*), where there was no stasis, the fibrinolytic indices of five animals at 0, 20, 90 and 180 min show an even distribution. Statistical analysis, using the Spearman rank test, shows no correlation between the fibrinolytic index and time. In the stasis group (*Table II*), the fibrinolytic index of each of the five animals shows a diminishing trend. The Spearman rank coefficient here shows a significant negative correlation between fibrinolytic index and time. This indicates a progressive reduction in fibrinolytic activity with stasis. *Table III* shows the mean values of fibrinolytic index in the two groups of animals in relation to the time of stasis. Further analysis using the Wilcoxon rank sum test shows that the two groups are significantly different at the 1 per cent level. At the end of 3 h of stasis the fibrinolytic index has been reduced to 31·58 per cent of the initial level.

Discussion

The fibrinolytic activity in the blood has been extensively investigated. However, this activity in the vein wall poses several difficulties for investigators.

1. Clinically, the vein that is readily available for study is often the long saphenous vein, obtained during varicose vein operations. These are abnormal veins and often have abnormal fibrinolytic activity. They cannot be assumed to be representative.

Table I: FIBRINOLYTIC INDEX IN CONTROL ANIMALS

Pig	Time (min) 0	20	90	180
1	12·45	10·06	4·38	6·79

Group	Time (min) 0	20	90	180
Control ($n = 5$)	14·31	8·21	11·8	8·64
Stasis ($n = 5$)	10·14	7·92	7·66	3·20

Wilcoxon rank sum test significant at 1 per cent level.

2. The small veins of the hand and foot are easily accessible and have been studied to a certain extent but one is limited by the small number of biopsies that can be taken and, therefore, changes in fibrinolytic activity cannot be followed.

3. A new method, devised by Johnson, measures the amount of lysis by its radioactivity released from ^{125}I-tagged fibrin clot (Johnson and Mansfield, 1978). Although this method is simple and quantitative, it is not very precise, for the published data revealed a coefficient of variance of 76 per cent. This method also requires a relatively large vein sample, which is not always obtainable.

4. The standard method for the study of tissue fibrinolytic activity is a qualitative histochemical technique developed by Todd (1958). Pandolfi et al. (1968) modified it by grading the lytic areas according to the degree of confluency. This semiquantitative method has been used frequently to study the fibrinolytic activity of the vein in physiological and pathological conditions (Browse, 1977). Since the process of grading is arbitrary and subjective, the precision of this method cannot be evaluated. Differences in data between studies cannot be easily resolved.

The method used in this study takes into account the total fibrinolytic activity contained in the tissue mass of the vein. Our unpublished data show that the fibrinolytic activity of the vein has a linear relationship with the weight of the vein ($r = 0{\cdot}93$, df $= 8$, $P < 0{\cdot}001$). This may mean that a bigger piece of vein contains a larger number of vasa vasoria where the plasminogen activator is thought to originate. The ratio of the area of lysis and that of the vein wall can be accurately measured. The counting of one area has low variability (coefficient of variance = 6 per cent). After estimating the fibrinolytic index of a very large number of sections from the same normal vein, the coefficient of variance for this method is 31 per cent ($\bar{x} = 9{\cdot}5 \pm 2{\cdot}9$, $n = 32$) when the sections are taken randomly, and 18 per cent when consecutive sections are obtained ($\bar{x} = 8{\cdot}7 \pm 1{\cdot}6$, $n = 30$). This suggests that the fibrinolytic activity at one point can be quite different from an adjacent point. We use random sections of vein in order to avoid misinterpreting our results. Todd's method has many variables. We keep the thickness of the fibrin overlying the vein section uniform by spreading a fixed volume of fibrinogen over a constant area. The other possible variable is the thickness of the vein section cut by the cryostat. The precision of this machine cannot be tested easily. Johnson and Mansfield (1978) showed that the rate of release of plasminogen activator varied greatly with the time of incubation. Pandolfi's method measures the concentration of plasminogen activator at specific active points along the vein and does not take into account the number of active points (Pandolfi et al., 1968). A large number of small lytic areas are graded lower than one bigger area. We chose the incubation time to be 1 h: this is short enough to be convenient and long enough for all the small lytic areas to be confluent. This eliminates another variable and facilitates the counting procedure.

Venous stasis is an important aetiological factor in the development of deep vein thrombosis. *In vivo* stasis is difficult to study as there had been a lack of a suitable experimental model. The method employed in our study produces intermittent stasis and offers an acceptable alternative. Our radiological and pressure studies confirm that the observed changes in fibrinolytic activity in the vein wall are not due to high venous pressure which is associated with venous occlusion. However, there is some low pressure dilatation of the distal venous tree due to the inflated cuff. We feel that this dilatation is probably an integral part of the physiopathological process of clinical venous stasis. Bauer (1940) performed venograms on a supine patient in whom deep vein thrombosis had been excluded. By raising the head of the operating table to 15° the deep veins were shown to be markedly distended. There was delay in the clearance of the contrast medium, indicating venous stasis. The cutaneous veins were also widened.

Venous occlusion results in an increase in the fibrinolytic activity in the blood (Clarke et al., 1960), which is thought to be due to a release of an activator substance from the store within the vein wall. Knight and Dawson (1976) used this phenomenon in an attempt to reduce the incidence of deep vein thrombosis following surgery, and Cliffton et al. (1961) used it to treat a case of superficial thrombophlebitis. Only 2 animals in our stasis group showed an initial rise in fibrinolytic index. After 3 h of stasis there is marked reduction in the fibrinolytic index. It appears that the so-called store of fibrinolytic activity is soon depleted. We have repeated the stasis experiment and subjected the endothelium to examination under the scanning electron microscope. The endothelial cells show evidence of damage within minutes of the onset of stasis (Wu, 1979). With prolonged stasis desquamation of endothelial cells occurs, followed by platelet aggregation. Since the endothelial cells contain a high concentration of plasminogen activator, we postulate that at least part of the depletion of fibrinolytic activity following stasis is due to the loss of endothelial cells into the circulation, resulting in a transient rise in fibrinolytic activity in the blood.

Our observation suggests that venous stasis could reduce the fibrinolytic activity in the vein wall by almost 70 per cent at the end of 3 h. This factor may increase the risk of the development of deep vein thrombosis and its hazards.

The incidence of deep vein thrombosis in Hong Kong Chinese after hip surgery for fracture of the proximal femur

C. K. MOK, F. T. HOAGLUND, S. M. ROGOFF, S. P. CHOW, A. MA AND A. C. M. C. YAU*

SUMMARY

Fifty-three Hong Kong Chinese patients with fractures of the proximal femur have been studied after hip surgery using functional ascending phlebograms for evaluating deep vein thrombosis. There was an incidence of deep vein thrombosis of 53·1 per cent in the fractured limbs and 14·3 per cent in the uninjured limbs. The majority of thrombi (84·6 per cent) were located in the calf. No clinical or fatal pulmonary embolism was observed.

A NUMBER of clinical reports, ^{125}I-labelled fibrinogen uptake studies and autopsy reviews suggest that there are differences in the incidence of thromboembolism between different geographical regions and different ethnic groups, with low incidences among Asian and African populations (Thomas et al., 1960; Franz et al., 1961; Dodd, 1964; Gore et al., 1964; Horn and Wang, 1964; Srivastava, 1964; Tinckler, 1964; Sevitt, 1965; Sandritter and Felix, 1967; Hwang, 1968; Baker and Houlder, 1973; Baker and Prajapat, 1974; Chumnijarakij, 1974; Cunningham and Yong, 1974; Hassan et al., 1974; Chumnijarakij and Poshyachinda, 1975; Bong and Chow, 1977; Talalak, 1976). However, Joffe (1974) from Cape Town and Colin et al. (1975) from Nairobi reported that European, Coloured, African and Indian patients were at a similar high risk of venous thromboembolism. True geographical and ethnic differences in the incidence of thromboembolism are of importance, because they might shed some light on the pathogenesis of the condition. A study on the incidence of thromboembolism in clinical practice amongst Chinese patients has never been reported. Clinical observations indicated that venous thromboembolism is a rarity even among 'high risk' Chinese patients (Horn and Wang, 1964; Bong and Chow, 1977). In an autopsy review (Hwang, 1968), the incidence of pulmonary embolism among Chinese in Singapore was found to be low. This article reports the use of phlebography to determine the incidence of deep vein thrombosis in a group of Hong Kong Chinese patients after hip surgery for fracture of the proximal femur.

Patients and methods

Fifty-three Hong Kong Chinese patients (19 males, 34 females), aged 40–83 years, with fractures of the proximal femur, were randomly selected for prospective study for deep vein thrombosis. Informed consent to perform the phlebography was given in writing by each patient. There were 19 intracapsular fractures and 34 pertrochanteric fractures. Pinning alone was performed in 6 patients, a pin and plate was used in 34 and a Moore's prosthesis was inserted in 13. Patients were not treated with aspirin or other antithrombotic medications during their care.

Functional ascending phlebography was performed principally according to the technique described by Rogoff and DeWeese (1960). After being reassured and coached in details of the procedure, the patient was placed semi-erect on an X-ray table raised to 45° from the horizontal. Percutaneous puncture or cut down was made into any convenient vein on the dorsum of the foot with a 20-gauge scalp vein needle. Infusion of isotonic saline was begun through a three-way stopcock to keep the needle patent. With a rubber tourniquet placed tightly around the ankle, 50 ml of Conray 280 (60 per cent meglumine iothalamate) were injected into the foot vein over a period of 1 min. At the end of the injection, the first exposure was made on a 14 × 34 in. (350 × 855 mm) film at 56 in. (1·4 m) target–film distance. The tourniquet was removed and the patient was instructed to pump up and down on the balls of his feet ten times. A second long radiograph was then exposed. The time lapse between the first and second radiographs was 35–40 s. A third 14 × 17 in. (350 × 427 mm) film centred under the pelvic region was exposed about 45 s after the second radiograph. The patient was then returned to a horizontal position and about 50 ml of saline were rapidly flushed through the needle. The phlebographic examinations were carried out 5–15 days after surgery and 7–28 days after the fracture. The timing of the examinations depended simply upon the availability of the patients and access to the radiological facilities.

All the phlebograms were read and interpreted by one of the authors (S. M. R.) who was unaware of the clinical status of the patients. The criteria for the diagnosis of venous thrombosis were based on those reported by DeWeese and Rogoff (1963), namely: (*a*) the recognition, in at least two radiographs, of well-defined defects in clearly visualized veins; (*b*) lack of opacification of the popliteal, superficial femoral or common femoral veins with good delineation of the proximal and distal veins, and the presence of collaterals. Absence of contrast medium in the calf veins was not considered diagnostic of thrombosis.

Examination for clinical evidence of deep vein thrombosis and pulmonary embolism was made daily by two of the authors (C. K. M. and A. M.). The patients' temperature charts were examined at the same time and attention was paid to any unexplained pyrexia. In the presence of any clinical signs which might suggest pulmonary embolism, a chest X-ray, an electrocardiogram, blood gases, serum bilirubin, serum glutamic-oxaloacetic transaminase and lactic acid dehydrogenase estimations were performed and repeated on subsequent days. Perfusion lung scan was only performed when there was a strong suspicion of pulmonary embolism.

Results

The phlebographic technique proved to be practical and relatively simple to perform. The films were of diagnostic quality, either excluding or demonstrating thrombus. A few patients experienced some discomfort in the foot and calf during the injection of the contrast medium. The discomfort rapidly disappeared after returning the patient to a horizontal position when saline was infused through the veins. There was no allergic reaction to the Conray 280.

Forty-five of the 53 patients who were being studied had bilateral phlebograms. The remaining 8 patients had unilateral phlebograms, 4 on the fractured side alone and 4 on the uninjured limb alone. Thus, there were 49 sets of phlebograms

performed upon injured limbs and another 49 sets upon uninjured limbs.

On reviewing the 49 sets of phlebograms from the injured limbs, thrombi involving the soleal veins were found in 8 patients, the posterior tibial vein in 2, the peroneal vein in another 2 and combinations of these veins in 9. Two patients had isolated clots in the common femoral and superficial femoral veins without calf involvement, and 3 other patients had involvement of both the femoral and calf systems. An incidence of 53·1 per cent of venous thrombosis was diagnosed on the injured limb phlebograms.

Seven (14·3 per cent) of the 49 sets of phlebograms of uninjured limbs were positive for venous thrombosis. There was one case each of soleal and peroneal vein thrombi, 2 patients had posterior tibial vein thrombi and a combination of calf vein involvement was present in 3 other patients.

Fifteen patients with phlebographic thrombi had clinical evidence of deep vein thrombosis; 11 other patients had clinical features of phlebothrombosis but showed no evidence of it on the phlebograms. Fourteen patients who showed evidence of a phlebographic defect had no clinical evidence of thrombosis. There was no diagnosed pulmonary embolism. Clinical features which remotely suggested pulmonary embolism were observed in 2 patients. Investigations, including perfusion lung scans, excluded the diagnosis. There was no hospital mortality in this group of patients.

Discussion

A group of patients with fracture of the proximal femur was selected for the study of venous thromboembolism among Chinese because the inhabitants of Western countries have a high incidence of venous thromboembolism. Despite the clinical observations of 'absence of thromboembolic complications' among Chinese patients with fractures of the proximal femur managed by non-operative (Horn and Wang, 1964) and operative (Bong and Chow, 1977) treatment, an overall incidence of 53·3 per cent of deep vein thrombosis was disclosed by the present phlebographic study. This is similar to that reported in the West (*Table I*).

When confinement to bed is taken as a risk factor, our patients were at a greater risk than similar patients in Western countries. In the present series, because of the lack of operating time, hip surgery was performed 2–14 days after the injury. Although clinical evidence of deep vein thrombosis was carefully sought, a confident clinical diagnosis of deep vein thrombosis was made on only two occasions in this prospective survey. An analysis of the clinical data collected and the phlebographic findings revealed no correlation between them. Inadequacy of the clinical methods probably explains the failure to recognize deep vein thrombosis in Chinese patients with fracture of the proximal femur by both Horn and Wang and Bong and Chow. Two unique observations of these authors remain, i.e. a low mortality rate (5·5 and 3·6 per cent respectively) and the absence of fatal pulmonary embolism. In the present study, when the sites of the thrombi are analysed and compared with similar studies in the West (*Table I*), the following points of difference are evident: (*a*) involvement of the uninjured limb is far less common; (*b*) the majority of thrombi are located in the calf; (*c*) extensive venous thrombosis is not observed. In the autopsy study on pulmonary embolism by Hwang in Singapore (1968), the incidence among Chinese was found to be low and massive emboli were rare. The low incidence of 'clots at risk' (Kakkar et al., 1969) among Chinese patients with fractures of the proximal femur probably explains the absence of clinical and fatal pulmonary embolism observed by us and others. It is felt that the differences demonstrated in this study merit further investigation.

Paper accepted 3 April 1979.

The average medical book is predominantly textual and illustrations are needed for two reasons: first, to represent something which the reader needs to be able to interpret by sight and not by a verbal description—something he will see in his work and recognize because he has seen it before, such as a measles rash as opposed to smallpox, a radiograph shadow, or a pathological cross-section; secondly, to clarify something which is obscure when expressed in words alone.

Medical illustrations are not designed primarily as decoration. The extent to which pictures are used instead of words can be a reflection of the author's verbal skills, but by and large it is he who originates the thought—the substance—of the book, and it is he who should decide whether it can be expressed best in words or in pictures.

Thyroid cancer: prognosis in 469 patients

M. D. STAUNTON AND R. G. SKEET*

SUMMARY

A computer study of 469 patients with thyroid cancer is presented. There were 40 per cent anaplastic, 30 per cent papillary, 15 per cent follicular and 15 per cent rarer tumours. The 20-year survival was 7·5 per cent for anaplastic, 55 per cent for papillary and 35 per cent for follicular carcinoma. The dominant role of histology in prognosis is confirmed.

Other important factors are: all patients under 45 reap benefit; females survive longer than males with papillary and follicular tumours. Cervical node metastases confer no depression in papillary tumours. Local tumour advance depresses survival but facilitates diagnosis. We find merit in the TNM classification, but warn against overelaboration.

We regret our failure to assess the differential effect of individual treatment, which poses a continuing challenge to oncologists.

ACCURACY in prognosis allows rational management of cancer. For common cancers, such as those of the lung or stomach, it required years of labour to achieve the present degree of knowledge of their behaviour. So much more difficult is it to reach the same level of knowledge about a rare cancer, such as that of the thyroid, with the added difficulty of its many variants. Thus, there is a need for reports on thyroid cancer from as many centres as possible, particularly from hospitals where relatively large numbers are treated and the patients are followed through life.

Patients and methods

A total of 535 patients with malignant neoplasms of the thyroid was treated at the Royal Marsden (formerly Royal Cancer) Hospital, London, between 1931 and 1972. Past reports on this work are listed elsewhere (Staunton and Greening, 1976). We studied all the original case notes and transferred the relevant facts to a proforma. At the South Thames Cancer Registry the information was analysed by computer. The follow-up information extends to 1976. Histological classification followed the principles of Meissner and Warren (1969). Professor Gowing reviewed all the original slides where the clinical course cast any doubt on the initial diagnosis. We excluded 66 cases of malignant adenoma, considering them benign (Staunton, 1976), and review here 469 patients with thyroid cancer.

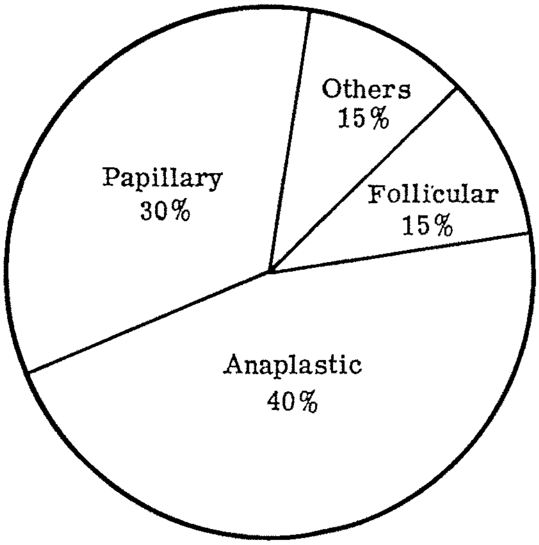

Fig. 1. Distribution of histological types.

Table I: AGE AND SEX DISTRIBUTION BY EACH TUMOUR TYPE

Type	Sex M	 F	Total	%	Average age (yr)
Papillary	41	106	147	31	45·6±2·8
Follicular	15	58	73	16	53·4±3·4
Anaplastic	49	116	165	35	61·9±2·1
Lymphosarcoma	3	29	32	7	60·8±5·8
Medullary	5	7	12	3	52·1±11·4
Fibrosarcoma	1	0	1	0	63·0
No histology	12	27	39	8	63·6±4·3
Total	126	343	469	100	55·3±1·6

Table I shows the number of each tumour type with the sex distribution and average age. The behaviour of those without histology confirms the clinical opinion that they were, in the main, anaplastic tumours. Thus, the approximate percentage of differing types was: anaplastic 40 per cent, papillary 30 per cent, follicular 15 per cent and others 15 per cent (these include lymphosarcoma and medullary carcinoma). We confine this report to the three main types shown in *Fig.* 1. The high percentage of anaplastic tumours makes the series unusual; only Scott and Halnan (1974) from Glasgow have a similar distribution. North American reports give papillary carcinoma an approximately two-thirds share, with anaplastic carcinoma the least frequent. Three reports from London (Greene, 1969; Taylor and Davies, 1970; Beaugie et al., 1976) also found papillary tumours to be most common. These differences call for comment. We know that in endemic goitre areas follicular carcinoma is the commonest type (Cuello et al., 1969) and in such areas, following iodine prophylaxis, an increasing papillary carcinoma rate is found (Heitz, 1976). Williams and Doniach (1976) made the interesting point that areas of high iodine content, such as Iceland, have a high percentage of papillary tumours in contrast to Aberdeen (low iodine), where anaplastic cancer is more frequent. It is well known that many differentiated tumours progress to anaplastic, so a 'late' series would contain a higher incidence of anaplastic than an 'early' one. Other factors could be the quirks of hospital selection and differences in histological classification. Whatever the reason, conflicting conclusions from differing series require careful scrutiny.

Various factors and their effect on prognosis were evaluated by computing actuarial survival rates and calculating the standard error at 5 years by the method of Greenwood (1926). The rates are 'minimum survival rates' since no account was taken of the fact that some deaths were due to causes other than thyroid cancer. For the detailed analysis the 5-year survival rate was used. Beyond 5 years, when the data had been divided into the various subgroups, the number of patients at risk was often too small to obtain reliable survival rates.

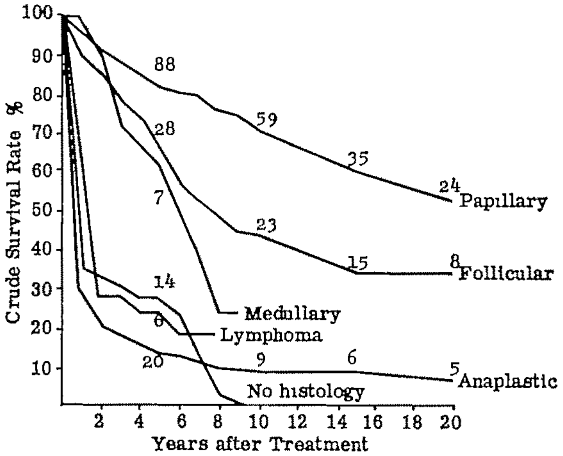

Fig. 2. Twenty-year survival rates by histological type.

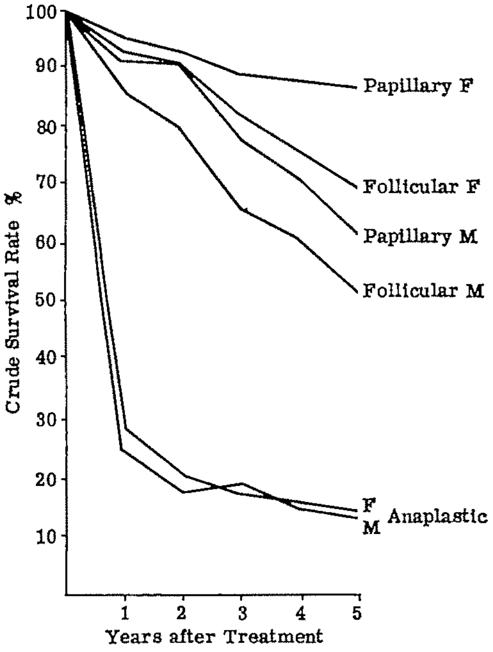

Fig. 3. Survival by histology and sex.

Fig. 2 shows the crude 20-year survival of this series (1931–72) in percentages, namely, papillary tumours 55 per cent (24 patients surviving), follicular tumours 35 per cent (8 patients surviving) and anaplastic tumours 7·5 per cent (5 patients surviving). The comparable figures of the 1931–61 series were 39, 23 and 4 per cent respectively (Staunton and Greening, 1976).

Results

The dominant role of histological type in prognosis was revealed by Woolner et al. (1961), and thus the findings in *Fig.* 2 cause no surprise but add further support to those authors' now classic account. The three main types of carcinoma gave statistically significant differences in survival: papillary better than follicular ($P<0{\cdot}05$), papillary better than anaplastic ($P<0{\cdot}0001$) and follicular better than anaplastic ($P<0{\cdot}0001$).

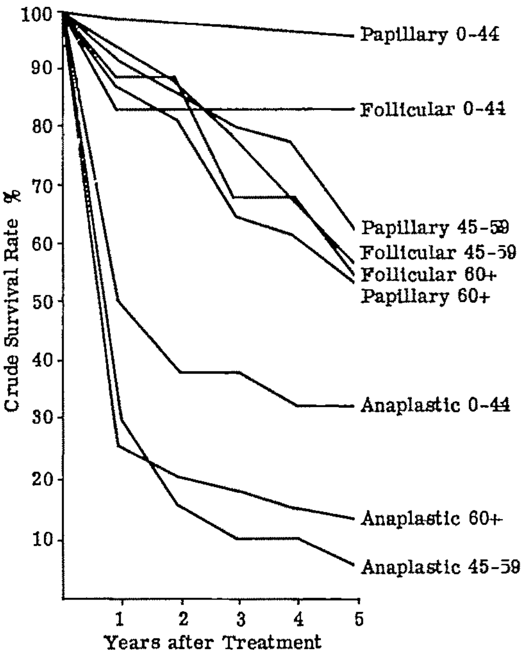

Fig. 4. Survival by histology and age group.

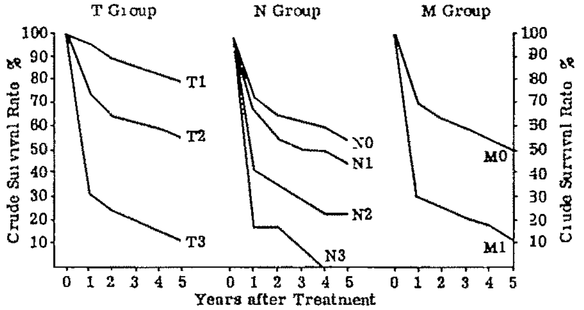

Fig. 5. Survival by TNM classification.

The part played by sex is illustrated in *Fig. 3.* Women with papillary tumours have a significantly longer survival ($P<0{\cdot}0001$). Females with follicular tumours seem to live longer but to a degree which just misses significance. In anaplastic carcinoma sex confers no benefit.

Fig. 4 shows the effect of age on survival rate, dividing the data into three age groups at 45 and 60 years. Crile's (1953) original opinion that age had a significant effect on survival was strongly supported in the young, i.e. those under 45. The survival of the young papillary group was significantly better than that of the middle aged or elderly ($P<0{\cdot}0001$); results were similar in follicular and anaplastic tumours ($P<0{\cdot}05$), granted the small number in the young anaplastic group. A new observation suggests that the middle aged have no improvement in survival over the elderly in any of the three types. Thus, age confers benefit only under 45 years and is not related to histology. The latter exercises a stronger effect, as shown in *Fig.* 4, where the worst (i.e. the oldest) papillary fare better than the best (i.e. the youngest) anaplastic.

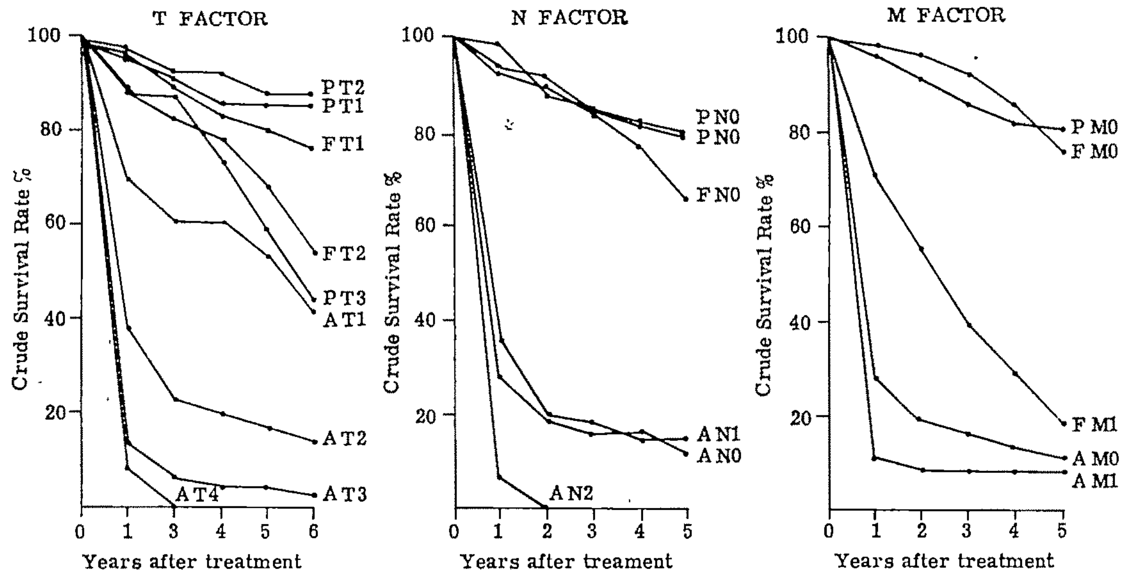

Fig. 6. Survival by histology and TNM classification.

Clinical factors

We give the computed 5-year survival rates by clinical findings in *Table II*. Patients with mobile tumours live longer ($P<0{\cdot}0001$) than those with either tethered or fixed tumours; those with tumours with smooth surfaces fared better ($P<0{\cdot}0001$) than those with nodular tumours; patients with tumours which were cystic or elastic did better ($P<0{\cdot}0001$) than hard tumours. From X-ray evidence it seemed that tracheal deviation or compression reduced survival ($P<0{\cdot}0001$), as also did vocal cord oedema or paralysis on laryngoscopy. Patients with tumours which were intrathyroid at operation lived longer than those with extrathyroid tumours ($P<0{\cdot}0001$).

The T (primary tumour), N (regional nodes), M (metastases) system of classification proposed by Denoix in 1953 was adopted by the International Union against Cancer (UICC) and applied to many sites, including the thyroid. *The TNM Classification of Malignant Tumours* (Geneva, 1968) is followed in this paper. After the XII International Congress in Buenos Aires (1978) a revised classification was published, based on the recommendations of the European Organization for Research on Treatment of Cancer (EORTC) and this may be found in the third edition of the booklet. We staged all patients where the case notes carried adequate details.

Fig. 5, taking all types of thyroid cancer together, gives survival by TNM. In T and M each stage carries a significant difference ($P<0{\cdot}0001$). In N the differences between N^0 and N^1 lacked significance; but N^2 behaved significantly worse than either ($P<0{\cdot}01$); while N^3 cases (fixed nodes) were too few for analysis. Taking a lead from the third edition of *The TNM Classification of Malignant Tumours* we staged our tumours under each histological type. *Fig.* 6 gives the results. This shows that T and M give worthwhile forecasting by emphasizing the perils of local advance and blood-spread metastases in all types. Again in both papillary and anaplastic tumours no significant difference occurs between N^0 and N^1, while lack of numbers precluded analysis of N^2 and N^3.

Table II: 5-YEAR SURVIVAL RATES BY CLINICAL FINDINGS

Sign or investigation	Findings	No. of cases initially at risk	5-yr survival rate (%)
Tumour mobility	Free	272	68
	Tethered	74	20
	Fixed	73	8
Tumour extent	Confined	302	61
	Extrathyroid	66	25
	Retrosternal	82	18
Stridor	Absent	423	52
	Present	62	18
Clinical assessment of cervical nodes	Impalpable	379	54
	Mobile	85	41
	Fixed	23	17
Consistency	Cystic	37	77
	Elastic	143	63
	Hard	207	28
Surface	Smooth	149	72
	Nodular	250	34
Oesophagus (barium swallow)	Normal	178	73
	Deviated	26	12
	Compressed	121	18
Trachea X-ray	Normal	104	75
	Deviated	185	43
	Compressed	44	11
Thyroid X-ray	Normal	24	65
	Abnormal	45	19
Laryngoscopy	Normal	263	69
	Oedema	31	13
	Cord paralysed	71	17

Pathology factors

Pure papillary and follicular tumours allow easy classification, but as many cases exhibit both elements many clinicians considered their segregation futile and reported the entire group as 'differentiated'. Woolner's (1961) plea for their divorce is well supported here. Eighty-two per cent of patients with tumours showing both elements survive to 5 years, similar to those with pure papillary tumours—establishing that the papillary element begets behaviour. Thus it is right to class as papillary all tumours exhibiting any papillary element.

We include Hürthle cell tumours under follicular and note the increased survival associated with them —78 per cent at 5 years against 63 per cent for the total follicular group. This differing survival justifies the continued identification of the Hürthle cell tumours and, should similar results be reported from other centres, then, from the view of prognosis, Hürthle cell tumours would be better classified among papillary tumours. The presence of anaplastic elements depresses survival among patients with papillary tumours to 40 per cent at 5 years and, among follicular tumours, to 30 per cent. Progression from differentiated to anaplastic has occurred in 19 patients, all dying from anaplastic metastases. The incidence of progression was 3 per cent in those treated without radiotherapy and 12·5 per cent in those with ($P<0·5$). Associated thyroiditis, shown histologically, conferred increased survival of 49 per cent at 5 years against 25 per cent in those without thyroiditis ($P<0·05$). The rate of mitosis exerted a powerful influence: where frequent, only 20 per cent survived 5 years as against 75 per cent where infrequent.

On the other hand, the following differences lack significance. Blood vessel invasion in patients with papillary tumours achieved a 70 per cent survival at 5 years against 80 per cent survival in those without invasion; blood vessel invasion in those with follicular tumours gained 72 per cent survival against 73 per cent in those without; lastly, those with anaplastic tumours with vessel invasion had 13 per cent survival against 17 per cent in those without. Capsular invasion was reported in only a quarter of cases, making analysis meaningless.

Nodal metastases were present in 47 per cent of papillary, 19 per cent of follicular and 46 per cent of anaplastic tumours. Five-year survival in these cases was 81 per cent, 61 per cent and 13·6 per cent respectively, in contrast to 73·4 per cent, 70·3 per cent and 11·1 per cent without node metastases. The differences lacked significance, confirming the view quite exceptional in oncology, that node metastases fail to depress survival; in fact, in papillary carcinoma they confer a slight advantage, possibly reflecting a high anti-tumour response rather than a late stage in the disease.

Discussion

Our results agree to a surprising extent with previous studies. Common histological classification allows comparison of like with like, disparities revealing areas for further investigation. Histology confirms that patients with papillary tumours survive longer than those with follicular tumours, and that both survive much longer than patients with anaplastic carcinoma.

Anaplasia confers increased malignancy in all cancers, therefore that it has a similar effect in the thyroid is not remarkable, but it is more difficult to explain why, with papillary tumours, prognosis is relatively good. A partial answer is because many such cancers occur under the age of 45, when age has a beneficial effect. This begs the question why should age exert a beneficial effect here when it does not do so in other cancers at the same age? We do not know, but the answer may be found in the hormonal factors surrounding and the high antigenicity contained in the papillary cell, manifest in the florid node metastases, such as feature in the young, and the favourable response to thyroxine. The differing prognosis of papillary and follicular tumours must be linked to their differing behaviour, e.g. the local displacement of surrounding tissues by follicular tumours against the infiltration of papillary tumour; the scarcity of nodal metastases with early blood spread so characteristic of follicular tumours as against early node metastases and late blood spread in papillary tumours. Histologically, the papillary tumour stimulates surrounding cellular reaction, notably absent in follicular tumours.

Another problem is the progression from low grade to anaplastic. This occurs in all cancers, but is more remarkable in the thyroid as it transforms the most docile of tumours into a lethal one. Why? The easy answer is continuing exposure to carcinogens. One proved carcinogen is radiation. The natural progression rate of 5 per cent (Thomas, 1972) fits well with the 3 per cent found here in those not given radiation, but 12·5 per cent found in those given such treatment must raise the question of whether the treatment increased the carcinogenic effect. The small numbers preclude any conclusion, but the message must be one of caution in the use of radiation for a tumour with a long natural history, particularly in a young person, unless other measures have failed.

Age

Most authors (Halnan, 1966; Bell, 1975; Russell et al., 1975; Cady, 1976) agree with Crile (1953) that increasing age carries an inverse relationship to survival. McKenzie (1971) found the effect limited to 'differentiated' tumours; Franssila (1975) agreed, but only in follicular cancers did this reach significance. Adding our own findings, the collective evidence points to a universal significant age factor before 45, exerting greater influence on papillary and follicular than on anaplastic types. Afterwards the effect wanes to insignificant levels in all cancer types.

Sex

Woolner et al. (1961), Halnan (1966), Hirabayashi and Lindsay (1961) and Beaugie et al. (1976) all failed to find any influence by sex on survival. Doll (1969), from a collective review, found with anaplastic tumours that male cases fared worse than female cases, but not to a significant degree; while with both papillary and follicular tumours the female advantage was significant. Franssila (1975) found that female patients with follicular tumours live longer, but not significantly so. Campbell and Sage (1975) and Cady (1976) found males to have reduced survival. We find, as did Doll (1969), that males with papillary tumours have a significantly improved survival, those with follicular tumours an improved survival, but not significantly so and in those with anaplastic tumours there is no advantage. Thus, the evidence fails to agree, but it may be a pointer that since Doll's report (1969) only one study has failed to find a relationship between females and prolonged survival in 'differentiated' tumours, but this effect is a lesser one than age.

At first we hoped to show the influence of treatment, in particular the role of surgery, on prognosis. To our disappointment, although we had large groups and comparable treatment groups, the large groups were not comparable and the comparable groups were too small to be significant. Nevertheless, we are heartened by the improved results here against those of the earlier series (1931–62), reflecting at least in part improved treatment. This merits further study.

Surgeons are well aware of the marked differences in survival between histological groups, but perhaps not so aware of the influences of age, local advance and the benign effects of nodes in papillary tumours—factors which are obvious on first encounter and critical on the ultimate outcome. Armed with these guidelines, the surgeon can match benefit against risk for the welfare of each patient.

Acknowledgements

We thank Mr R. W. Raven, Sir David Smithers, Mr M. H. Harmer and Mr W. P. Greening who gave permission to publish their cases and were a source of continuous help and inspiration. Thanks also go to Miss M. Martin, who designed and carried out the computer conversion, to Miss Susan Taylor and Mrs E. Strong for retrieval of records and to Professor Noel Gowing for generous advice.

Hyperparathyroidism in pregnancy

RICHARD SALEM AND SELWYN TAYLOR*

SUMMARY

Primary hyperparathyroidism in pregnancy is uncommon and easily overlooked. It is associated with a complication rate of up to 80 per cent—mainly stillbirths, abortions and neonatal tetany. Surgical treatment during pregnancy offers the best chance for fetal and neonatal survival.

HYPERPARATHYROIDISM occurring during pregnancy is very rare. However, this entity may be recognized more frequently with the routine use of the automated biochemical analyser.

This disease is associated with high maternal and fetal morbidity and of great importance is the apparent lack of awareness by many doctors that hyperparathyroidism can occur during pregnancy. We report here 3 cases that illustrate most of the features of this condition.

Case reports

Case 1: C. K., a 24-year-old Indian, was transferred to Hammersmith Hospital on 24 April 1975, 2 weeks after a Caesarean section at term for transverse lie. She had been perfectly fit but developed progressive weakness and fatigue during the pregnancy and during the last trimester complained of pains in the ribs, hips and back. On the fifth day post partum her baby developed some 'twitching' and was found to be hypocalcaemic. It was only at this stage that the mother was investigated and found to be grossly hypercalcaemic.

On admission she was extremely ill and complained of thirst, nausea and skeletal pains. She was emaciated and had a small swelling on the right side of her neck in the thyroid region. There was marked hyper-reflexia and bony tenderness, and she was unable to lift her limbs from the bed.

Relevant investigations were as follows: serum calcium 3·8 mmol/l (normal 2·15–2·65); serum phosphorus 1·1 mmol/l (normal 0·8–1·4); total proteins 66 g/l (normal 65–80); alkaline phosphatase 1155 i.u./l (normal 30–130); serum magnesium 0·3 mmol/l (normal 0·8–1·2). X-rays of her hands showed marked subperiosteal erosions, bone resorption and early cyst formation and X-ray of the skull showed a classic 'pepper-pot' effect.

An attempt to control her hypercalcaemia was made using calcitonin intravenously, a fluid diuresis and oral phosphates. Her magnesium deficiency was also corrected. However, despite good rehydration, the calcium level could not be controlled and on the third day after admission surgical exploration of the neck was performed. A parathyroid adenoma 3×2·5×2 cm was removed from the lower right position. Postoperative recovery was complicated by hypocalcaemia which was controlled with calcium gluconate i.v. and she received oral calcium and vitamin D for a further 2 months. Her recovery was complete and she remains normocalcaemic. In 1978 she had a normal pregnancy and delivery with no complications.

Case 2: G. K., an Indian doctor, had had three previous miscarriages before the present pregnancy which was also complicated by a threatened abortion at 11 weeks and a premature birth at 35 weeks. Three days post partum the baby developed tetany, due to hypocalcaemia. Investigation of the mother showed a normal serum calcium and phosphorus level and a raised alkaline phosphatase. She was thought to have mild osteomalacia due to an inadequate intake of vitamin D during her pregnancy, and she was treated with a short course of the vitamin.

Two months after completing this course her serum calcium level had risen to 2·8 mmol/l (normal 2·15–2·65) and her serum phosphorus was at the lower limit of normal. The results of other biochemical estimations were normal. The serum parathyroid hormone (PTH) level was 1·1 μg/l (normal <0·75). A diagnosis of primary hyperparathyroidism was made and, at operation, a small parathyroid adenoma (0·5×0·4×0·2 cm) was removed from the left upper position. The patient made a satisfactory recovery and her serum calcium remains in the normal range.

Case 3: A. C., a 36-year-old English woman, had had two normal pregnancies—the last 11 years previously. During 1976 and 1977 she had had several attacks of renal colic and was eventually investigated and found to have hypercalcuria and mild hypercalcaemia (Ca^{2+} 2·7 mmol/l) thought to be due to mild primary hyperparathyroidism. The serum calcium levels were controlled at that time by dietary measures alone. However, when she became pregnant it was felt that she should have surgical treatment of the hyperparathyroidism and at 22 weeks' gestation she had an adenoma of the parathyroid (1·5×0·7×0·5 cm) removed from the left lower position. Apart from a little temporary hypocalcaemia which was treated with oral calcium supplements she made an uneventful recovery. She continued on oral calcium for the rest of her pregnancy and had a normal delivery at full term of a healthy female baby. There were no neonatal complications.

Discussion

Calcium metabolism undergoes widespread changes in the mother during pregnancy which are reflected by a rise in the level of calcitonin throughout and also of PTH in the latter half of the pregnancy. In addition, calcium absorption from the gut is normally increased in order to compensate for the transfer of 20–30 g of calcium from mother to fetus, mostly in the last trimester. It is not surprising therefore that a rise in circulating PTH due to a parathyroid adenoma is likely to have severe consequences in a patient whose skeleton is already being depleted by the demands of the fetus. If, in addition, the patient is lacking in vitamin D because of an inadequate intake in the diet and lack of sunshine then the health of both mother and fetus is endangered.

While calcium ions move freely across the placenta, serum PTH cannot cross from mother to fetus (Garel and Dumont, 1972; Northrop et al., 1974). Raised maternal calcium levels therefore cross the placenta and cause an increased circulating calcium concentration in the fetus (Wagner et al., 1964) and this in turn will cause suppression of the fetal parathyroids (Sinclair, 1942; Bruce and Strong, 1955).

Bakwin (1937) suggested that the fall in fetal circulating calcium which occurs shortly after birth is due to underactivity of the parathyroid in the newborn which is related to the physiological hyperactivity of the maternal parathyroid during pregnancy. Friderichsen (1939) described tetany in a 5-month-old suckling baby which led to the diagnosis of hyperparathyroidism in the mother, and Talbot et al. (1952) and Walton (1954) described neonatal tetany in children of hyperparathyroid mothers.

Neonatal tetany drew attention to the correct diagnosis in our *Cases* 1 and 2.

Table I: PARATHYROIDECTOMY DURING PREGNANCY: REPORTED CASES

Author	Symptoms	Gestation at time of op.	Maternal complications	Neonatal complications
Petit and Clark (1947)	Renal colic	6 mth	None	None
Whalley (1963)	Polyuria, renal stones, weakness	6 mth	Spout-abortion, hypocalcaemic	Macerated fetus
Goldsmith et al. (1966)	Bone pain	N.S.	Tetany	N.S.
Rubin et al. (1968)	Asymptomatic	2nd trim.	None	None
Findlay (1969)	Renal colic	24 wk	Pre-eclamptic toxaemia at 38 wk	None
Dobbelstein et al. (1970)	Thirst, weakness	7 mth	Hypocalcaemia	None
Johnstone et al. (1972)	N.S.	3 mth	Tetany, Caesarean section (disproportion)	None
Beal (1974)	Nausea, vomiting, lethargy	2 mth	N.S.	None
Pedersen and Permin (1975)	Renal colic	14 wk	Normal delivery at 36 wk	None
Dorey and Gell (1975)	Bony tenderness	37 wk	Hypocalcaemia	None
Molinatti et al. (1975)	Asymptomatic	7 mth	Hypocalcaemia, Caesarean section (tranverse lie)	None
Delmonico et al. (1976)	Asymptomatic	4 mth	Caesarean section (disproportion)	None
Gaeke et al. (1977)	Hypertension, nephrocalcinosis	17 wk	Hypocalcaemia	None
Present case	Renal colic	20 wk	Hypocalcaemia	None

N.S., Not stated; trim., trimester.

Case 1 illustrates how symptoms of hyperparathyroidism may be overlooked and blamed on 'the pregnancy' or 'nerves'. Pedersen and Permin (1975) noted that hyperemesis gravidarum may be associated with primary hyperparathyroidism. *Case* 1 also shows how, in the extremely ill patient, attempts to lower the calcium medically are only temporary and may buy a little time before definitive treatment, but if there is no immediate response then parathyroidectomy must be undertaken as a matter of extreme urgency.

Ludwig (1962), in his review of the literature, found a complication rate of 50 per cent in 40 pregnancies in 21 mothers with primary hyperparathyroidism (stillbirths, spontaneous abortion, neonatal deaths 31 per cent, neonatal tetany 19 per cent). Delmonico et al. (1976) found the complication rate to be 80 per cent in the 13 cases described.

Case 2 illustrates many of these complications, i.e. miscarriages, threatened abortion, premature birth, neonatal tetany. This case also shows how the diagnosis of hyperparathyroidism may be masked biochemically by osteomalacia due to deficiency of vitamin D in the diet.

That surgical treatment of primary hyperparathyroidism can be undertaken during pregnancy is shown by *Case* 3. Since Petit and Clark (1947) described their successful removal of a parathyroid adenoma during pregnancy there have been a further 13 similar cases (including our own) described in the literature (*Table I*). In these 14 cases complications have been few. In Whalley's case (1963) spontaneous abortion of a macerated fetus occurred the day after parathyroidectomy which was performed for a hyperparathyroid crisis with associated renal stones and hypertension in which the fetus was dead before operation. There were no other neonatal complications in this group, except hypocalcaemia without tetany in Delmonico's case (Delmonico et al., 1976).

Maternal postoperative hypocalcaemia required treatment in at least 8 of these 14 cases, indeed tetany developed in 2 cases. We would advocate careful postoperative monitoring of the serum calcium level and treatment with calcium supplements should the calcium fall below the normal range even if symptoms of hypocalcaemia are not present. With such a high risk of maternal hypocalcaemia perhaps calcium supplements should be given routinely and continued for the rest of pregnancy.

It would seem that operative treatment of hyperparathyroidism in pregnancy is the treatment of choice, reducing considerably the neonatal morbidity.

Bilateral axillary artery aneurysms in a child

J. A. DORMANDY AND THE LATE H. BARKLEY*

Case report

Two pulsating lumps were noticed in the axillae of a 10-month-old boy. He had no relevant past history except for a severe encephalitis requiring 3 weeks' hospitalization a month before the appearance of the axillary lumps. On examination the lumps were clearly fusiform aneurysms of the axillary arteries and as the right aneurysm was said to be enlarging, it was explored when the child was 1 year old. A well-localized fusiform true aneurysm was found, surrounded by the trunks of the brachial plexus. When the aneurysm was opened through a longitudinal arteriotomy, it appeared to have a normal adventitia with a thick, white, organized mucinous core (*Fig.* 1). This core seemed to merge with the normal-looking inner layers of the entry and exit vessels. Since the defect was very localized, the aneurysm was resected and the artery reconstructed, using the trimmed normal-looking adventitia and outer layer of the media. The child made an uneventful postoperative recovery.

Histology showed that the inner wall of the aneurysm consisted of loose myxomatous tissue composed of fibrocytes with oval or stellate nuclei and associated fine collagen fibrils separated by a mucinous background which stained strongly with alcian blue. The external wall consisted of media and adventitia, with only a little overlying intima, this last showing changes as described above. There was marked disorganization of the media, with severe degeneration and loss of elastic and muscle fibres, those remaining being separated by a mucinous background. The adventitia was moderately thickened by mature collagen. The vasa vasorum appeared normal and there was no evidence of inflammation. The appearances were those of fibromuscular dysplasia with aneurysm formation.

This case did not have the characteristic clinical features of any recognized type of aneurysm. Congenital aneurysms are usually saccular herniations of the inner layer and are almost always in the cerebral vessels. There were none of the clinical features of either the Marfan or the Ehlers–Danlos syndrome. There was no history of trauma and the aneurysms were not false. Cystic medial necrosis is very rare at this age and almost always affects the aorta. There was no biochemical evidence of either haemocystinuria or a lipodystrophy. As the aneurysms were first noticed shortly after the encephalitis, mycotic aneurysms had to be considered, although these are very rarely due to viral emboli and almost always result in a false aneurysm at a bifurcation of an artery.

Histological evidence strongly suggests that these aneurysms formed on the basis of arterial fibromuscular dysplasia. Similar histological appearances have been described in the basilar artery of an 11-year-old girl who died when the aneurysm ruptured spontaneously (Hirsch and Roessmann, 1975). A 16-month-old boy died following thrombosis of a carotid artery and was also found to have a fusiform aneurysm of the brachial artery due to fibromuscular dysplasia (Duffy et al., 1957). Similar appearances have been described in the neck arteries of 3 other children (Bostrom and Liliequist, 1967), but four-vessel angiography showed no abnormality in our case. The patient still has the axillary aneurysm on the left and the best treatment for this remains uncertain as we were unable to find any information about the natural history of such lesions. Whether the type of plastic reconstruction used on the right is the preferred technique is also debatable; an autologous vein graft may have been a better procedure.

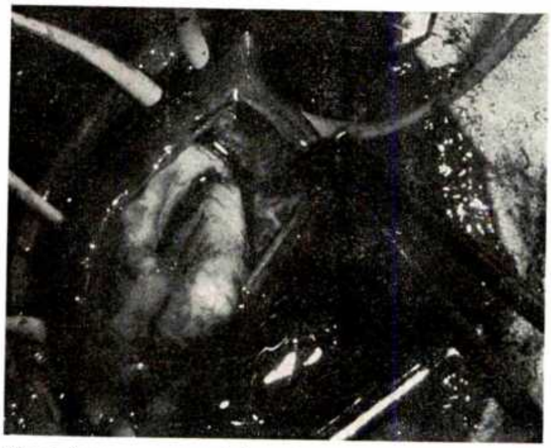

Fig. 1. Aneurysm opened through a longitudinal incision. This thickened inner layer has been cut across and half removed. Branches of the brachial plexus can be seen surrounding the aneurysm.

A technique for the difficult peripheral arterial aneurysm

W. E. BIRKENSTOCK*

SUMMARY

Complete external control of the vessels feeding some aneurysms may be very difficult and occasionally only achieved at the cost of damage to surrounding structures. A method is described in which Foley catheters are introduced into the feeding vessels from within the aneurysm and then cut distal to their clamped side branch to enable Dacron grafts to be passed over them and sutured in place. This technique has been used in 3 patients with very satisfactory results and is offered as an alternative when standard control is hazardous, or impossible.

SURGERY of most aneurysms is reasonably routine and follows basic principles of proximal and distal control followed by reconstitution with or without resection of the aneurysm. Most aneurysms are atherosclerotic and there is little reaction surrounding the proximal or distal vessels, making control relatively simple. In traumatic aneurysms or ruptured small vessel aneurysms, however, there is often surrounding fibrosis, haemorrhage and adjacent vital structures making the dissection more difficult. These factors may lead to extensive dissections with injury to surrounding structures.

Bole pointed out that, in a case of a false aneurysm of the abdominal aorta, a direct approach to the aortic defect through the aorta and repair from inside the lumen could avoid a tedious and often hazardous dissection around the thin-walled aneurysm or through the marked surrounding reaction (Bole et al., 1975). Robicsek et al. (1970) also described the use of a balloon catheter to obtain control in difficult abdominal aortic aneurysms.

The technique described here can be used for most traumatic aneurysms of large or small vessels, but is of particular usefulness in small vessel aneurysms where the difficulties already mentioned exist. Three cases are presented to illustrate the technique.

Case reports

Case 1: This patient was a 68-year-old man who had an indurated pulsating swelling behind his left knee. While awaiting elective surgery he developed acute pain behind the knee and was found to have ruptured the aneurysm with external haemorrhage and extensive soft tissue extravasation. Haemorrhage was controlled by local pressure but proximal control of the artery was difficult due to extravasation and was only obtained by exposure and clamping of the artery in the thigh. The distal vessels could not be found. The aneurysm was opened and bled briskly from both proximal and distal arterial orifices, coming evidently from geniculate collateral arteries. No. 10 Foley catheters were introduced into both proximal and distal arterial orifices and the cuffs inflated to control bleeding. Heparin solution was injected into the vessels via the Foley catheters which were then occluded by bulldog clamps (*Fig.* 1).

A circumferential incision was made approximately 1 mm from the orifices of the feeding and draining vessels through the wall of the aneurysm and the artery was identified as it entered and left the aneurysm. (The small cuff of aneurysm at each ostium made the anastomosis with a graft much simpler.)

Bulldog clamps were then applied to the Foley catheters near the orifice of the artery, and the catheters were divided

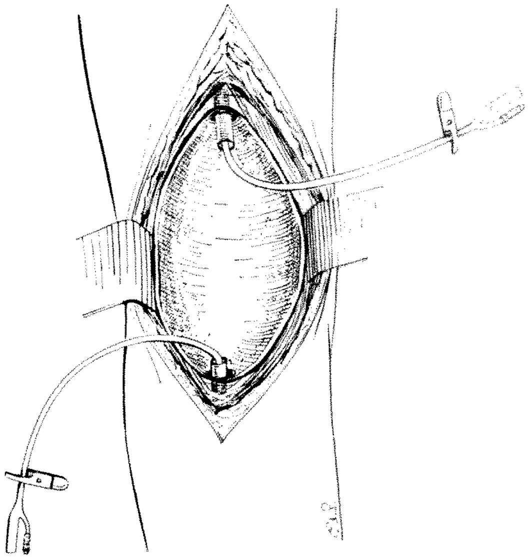

Fig. 1. The open aneurysm and proximal and distal arterial cuffs with Foley catheters inserted to effect control.

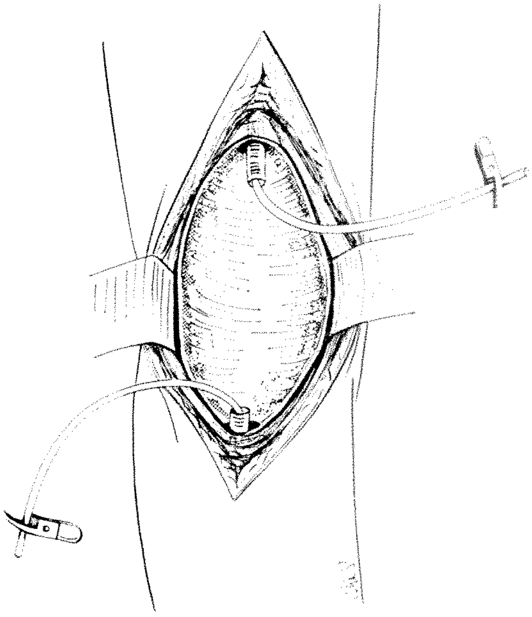

Fig. 2. The Foley catheters have been cut to allow passage of the graft. The clamps should be closer to the arterial cuff.

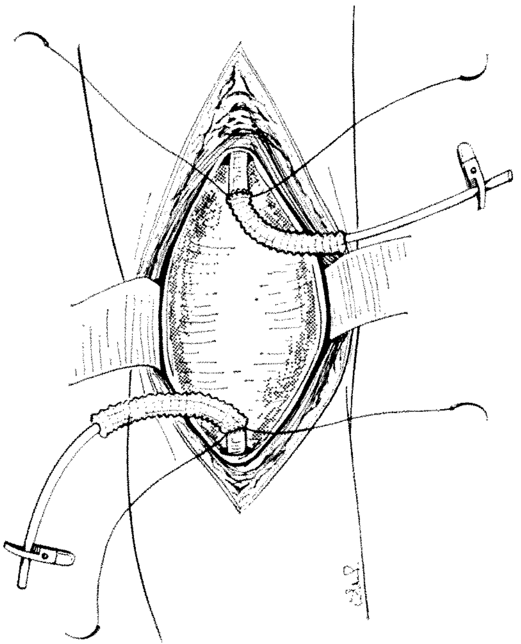

Fig. 3. The grafts, having been slipped over the free end of the catheter and the clamps applied distally, are now sutured to the arterial cuff.

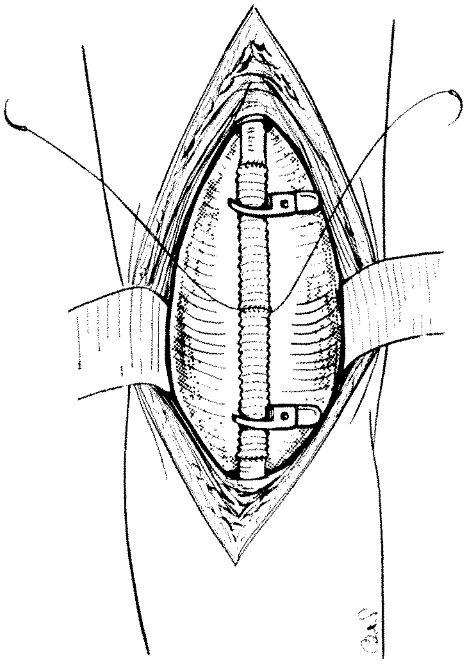

Fig. 4. Showing the completed anastomosis.

near the inlet of the bulb sideline (*Fig.* 2). Dacron grafts were then slid over the Foley catheters and a further bulldog clamp applied to the catheter as it emerged from the graft so that the previous bulldog clamp could be removed, the graft slid down to the cuff and anastomosed end to end to the artery as shown in *Fig.* 3.

The Foley catheters were then deflated and withdrawn while bulldog clamps were applied to the grafts near the anastomosis

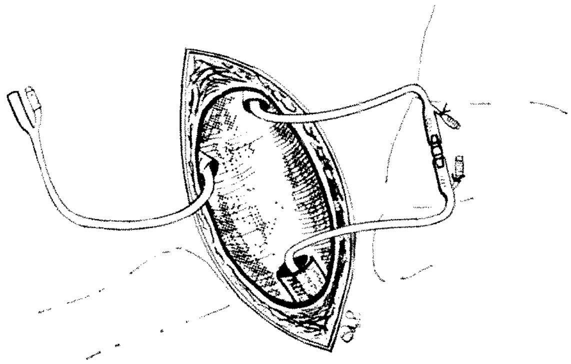

Fig. 5. As in *Case* 2, where three vessels were involved and a bypass was introduced.

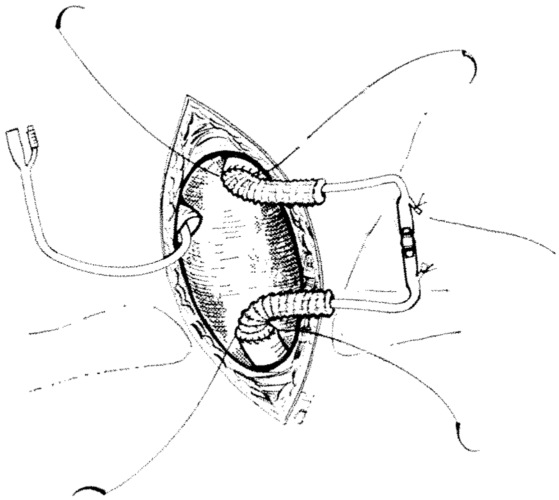

Fig. 6. The main flow anastomosis is nearing completion with bypass flow still functioning.

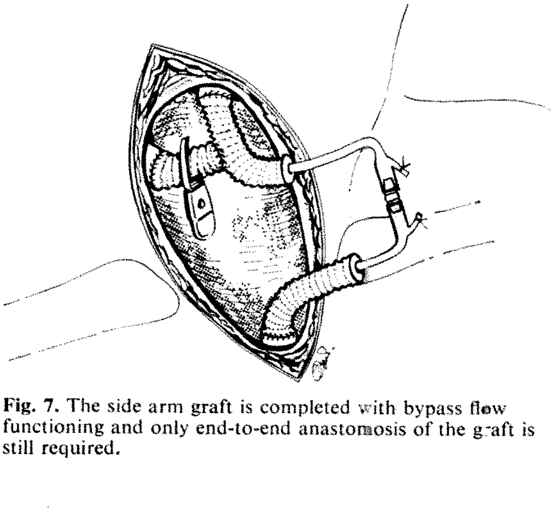

Fig. 7. The side arm graft is completed with bypass flow functioning and only end-to-end anastomosis of the graft is still required.

with the arterial cuff. The grafts were then trimmed to the desired length and sutured end to end as shown in *Fig.* 4 to complete the arterial reconstruction.

This technique is applicable to varying circumstances and can be modified to cope with the problem of more than two vital arterial orifices opening into the aneurysm.

Case 2: A young man who had been shot in the base of the neck developed a traumatic aneurysm involving the bifurcation of the innominate artery. Dissection of the aneurysm would have proved extremely difficult in view of the neighbouring brachial plexus, phrenic and vagus nerve trunks. At the same time some method of bypass to maintain carotid flow was deemed advisable. Here a modification of this technique proved of great benefit.

After control of the innominate artery via a thoracotomy incision, the aneurysm was opened and Foley catheters were introduced into the orifices of the innominate, carotid and subclavian arteries and inflated. The bulb-inflating sidelines of the innominate and carotid catheters were then tied off and the sideline excised. These two catheters were then joined with a tapered plastic connector and the bulldog clamps removed, allowing bypass flow into the carotid artery (*Fig.* 5). Circumferential dissection around the orifices of the involved arteries was a reasonably simple matter and the required grafts were then slid over the Foley catheters with temporary interruption of the bypass. Once the anastomosis of the two arteries to the two graft sections had been completed (*Fig.* 6), the bypass was again temporarily interrupted, the Foley catheters removed and the grafts trimmed and sutured end to end. This latter procedure was completed well within the accepted time for possible cerebral ischaemia. With adequate carotid flow restored, the subclavian artery orifice was dissected out and a graft sutured to it. The Foley catheter was removed, the side arm graft clamped and sutured end to side to the previously completed carotid graft.

The one point of difficulty in the second case arose from the time taken in anastomosing the subclavian graft to the carotid graft. It was realized that by altering the procedure slightly, this problem could be overcome and it is suggested that in such a case the side arm graft be anastomosed to the main graft before suturing the main graft to the arterial orifice. The Foley catheter from the side arm would be passed through the side arm graft and out of the main graft orifice with the main graft Foley catheter. The side arm graft can then be anastomosed to the side arm arterial cuff and the side arm catheter removed and a bulldog clamp applied to the side arm graft (*Fig.* 7). The two main grafts can then be sutured as previously described without any extra interruption of flow through the main graft.

Case 3: A 33-year-old man was referred to us 14 days after being stabbed above the right clavicle. He presented with an enlarging pulsatile swelling in the posterior triangle. There was some neurological deficit involving C5 and C6. No bruit was audible and arteriography showed an aneurysmal dilatation of the right subclavian/axillary artery just lateral to the first rib.

The aneurysm was approached via a supraclavicular incision and the feeding vessel controlled by digital pressure. The aneurysm was opened and backflow from the distal orifice initially stopped by direct pressure. Foley catheters were introduced into both orifices and the bulbs inflated with complete control of bleeding. In this case there was still a posterior wall of artery intact and the cuff was so dissected out to allow end-to-end reconstitution of the artery without the use of a graft. Prolene sutures were inserted with the Foley catheters in place and the catheters removed to allow the final closure of the anastomosis while digital control of the feeding vessel was applied.

Discussion

Although the treatment of traumatic or ruptured peripheral arterial aneurysms may be relatively straightforward, it often involves prolonged and tedious dissection to obtain control of the feeding and draining vessels. Especially in the carotid, subclavian, axillary and inguinal areas, where many of these traumatic aneurysms occur, the neighbouring vital structures can easily be damaged, resulting in permanent loss of function, and some method which would obviate this hazard would be very helpful.

It is obviously desirable that some form of proximal control should be achieved when possible in aneurysms where loss of control due to failure of the catheter would be catastrophic, e.g. control of the innominate artery in *Case* 2. Some surgeons are prepared to operate on the carotid artery without a bypass provided that angiography has shown adequate cross flow from the opposite side. There still remains, however, a small percentage of patients who develop cerebral ischaemia on occlusion of the carotid. In Rittenhouse's review it was stated that 24 per cent of patients who had occlusion of the carotid artery developed a neurological complication (Ritterhouse et al., 1972). Arpin et al. (1975) pointed out that extracranial carotid aneurysms of any aetiology were very rare, but when they do occur, they can result in tragic consequences if the patient should develop cerebral iscahemia during the operative procedures. Some form of bypass should make such operations safer provided that, as in the method here described, it is simple and not likely to cause complications in itself.

It is suggested that this method will be found to be applicable in varied circumstances and that where standard methods may prove hazardous, this technique could result in safer and quicker operations.

Noxythiolin (Noxyflex), aprotinin (Trasylol) and peritoneal adhesion formation: an experimental study in the rat

A. T. RAFTERY*

SUMMARY

Clinical and experimental studies have suggested that noxythiolin and aprotinin may prevent intraperitoneal adhesion formation. A comparison was therefore made of their efficacy in preventing the reformation of adhesions following surgical lysis in a controlled trial using rats. Neither noxythiolon nor aprotinin had any significant benefit over surgical lysis alone. The mortality rate was high in the noxythiolin-treated group.

INTRAPERITONEAL adhesions are a common cause of intestinal obstruction (Ellis, 1974). Numerous methods have been tried over the years in an attempt to prevent adhesions, but with little success, despite initial enthusiastic reports. Recently, two further substances have been reported as efficacious in decreasing the incidence of intraperitoneal adhesions, namely noxythiolin (Noxyflex, Geistlich) and aprotinin (Trasylol, Bayer). Following the observation of Tolhurst Cleaver et al. (1974) that adhesions occurred less frequently in rats given intraperitoneal lavage with noxythiolin than those given lavage with Hartmann's solution, Gilmore and Reid (1976) showed that a single intraperitoneal dose of noxythiolin reduced the incidence of adhesions in rats. Experimental studies (Vorster, 1968; Grundmann, 1969) have shown that aprotinin reduces the incidence of adhesions and Mooney (1976) has shown a reduced incidence of adhesions in a clinical study. However, these studies all relate to prevention of adhesions at an initial laparotomy. As Ellis (1971) has pointed out, the vast majority of adhesions are harmless and may well be protective or even life-saving to the patient, for example in protecting an anastomotic line in which the blood supply was endangered or in localizing infection. In the study reported here no attempt was made to prevent adhesions forming following the initial laparotomy, but, following a second laparotomy to divide the adhesions created at the initial laparotomy, either noxythiolin or aprotinin was instilled into the peritoneal cavity in order to assess the efficacy of these substances at preventing the reformation of adhesions.

Materials and methods

Adult male Sprague-Dawley rats weighing 250-300 g were used in this investigation. Anaesthesia was induced with ether and maintained with a nitrous oxide, halothane and oxygen mixture. At the initial laparotomy the abdomen was opened through a midline incision 5 cm long. Adhesions were created by a method of multiple peritoneal trauma. The operative techniques were as follows.

A defect 2 cm × 0·5 cm was made in the left flank, involving removal of the peritoneum and underlying layer of muscle within this area. The defect was repaired with a continuous 3/0 chromic catgut suture. A similar defect was made on the right flank, but this was not sutured. The caecum was delivered from the wound and its surface rubbed briskly with sterile gauze until petechial haemorrhages were observed. The peritoneum at the ileocaecal junction was grasped between forceps and stripped off the antimesenteric border of the ileum for about 5 cm from the ileocaecal junction (Glucksman, 1966), removing a strip of peritoneum about 1 mm wide and also the underlying layer of longitudinal muscle. The abdominal incision was closed in two layers, catgut sutures being placed through the musculoperitoneal layers and silk sutures through the skin.

The rats were subjected to a second laparotomy 2 weeks later. The position of all adhesions was noted and the adhesions divided with scissors. At the end of this procedure, just prior to closure of the abdomen, 2·5 ml of one of a batch of numbered solutions (1–100) was instilled into the peritoneal cavity. Surviving animals were killed 2 weeks later and inspected for adhesions. The position of all adhesions was noted. At completion of the experiment the number code of the solutions was broken. In total, 120 animals were operated on and 100 received an intraperitoneal solution at the completion of the second laparotomy. The following solutions were instilled into the peritoneal cavity: 20 rats received 2·5 ml of normal saline, 20 received 2·5 ml of 2·5 per cent Noxyflex (noxythiolin + amethocaine), 20 received 2·5 ml of 2·5 per cent Noxyflex S (noxythiolin alone), 20 received 25 000 units of aprotinin and 20 received 50 000 units of aprotinin. Statistical analysis of the results was carried out using Fisher's exact test.

Results

Some adhesions formed in each animal following the initial laparotomy. As each group of animals acted as their own 'controls' in assessing the results of the various treatments, statistical analysis was carried out to assess whether there was any significant difference between the number of adhesions in each control group prior to treatment. None was found.

The sites of adhesion formation and the number of animals having adhesions at the various sites are shown in *Tables I–VI*. Following the second laparotomy there was a significantly increased mortality in the group treated with Noxyflex ($P<0{\cdot}001$) and also in the group treated with Noxyflex S ($P<0{\cdot}005$). None of the treatment groups showed a significant reduction in adhesions compared with surgical lysis alone. On the contrary, there was a significant increase in adhesions to the left flank in the group treated with Noxyflex S ($P<0{\cdot}005$). It was not possible to evaluate statistically the effect of Noxyflex on adhesions due to the high mortality in this group. Post-mortem examination of the 2 rats that died in the saline-treated group showed that death occurred from peritonitis resulting from caecal volvulus and gangrene of the caecum. All the rats that died in the groups treated with Noxyflex and Noxyflex S did so within 48 h of operation. Limited post-mortem examination revealed no abnormality in the peritoneal cavity, but showed bilateral pleural effusions and haemorrhagic lesions in the lungs.

Discussion

The results show that none of the substances used in an attempt to prevent adhesions has a clear advantage

NEW Recording Phonoangiograph

(CPA) for Cerebral Vascular evaluation

The major diagnostic CPA parameters are absence or presence of 1st and 2nd heart sounds, absence or presence of high-frequency content in systole or systole and diastole, and the differential character of the three traces taken on each side.

The sensitivity, amplification, quantitation, and frequency range of CPA is well above the capacity of the human ear. This allows appreciation of bruits that cannot be heard with a stethoscope. The advantages of quantitation and hard copy are obvious.

CPA is helpful even for the experienced examiner in identifying transmitted murmurs.

Patient groups most often suggested for routine Cerebral Vascular Evaluation include:

a) Hospital admissions over 60 years of age.
b) Patients undergoing cardiopulmonary bypass.
c) Patients with multiple risk factors for arteriosclerotic disease.

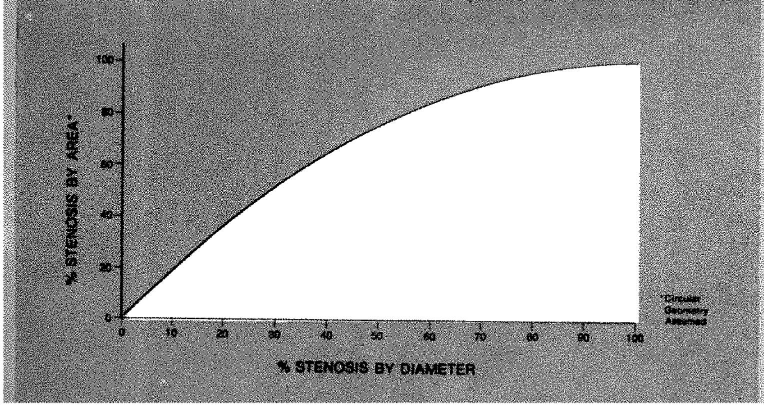
% STENOSIS Dia. By Ar	DESCRIPTION	CPA TRACING
	1) Normal 1st and 2nd heart sounds with no significant audiofrequency content (amplitude, intensity) during either systole or diastole. Note: absence of only the 1st heart sound does not suggest abnormal carotid artery pathology	
	2) The first heart sound is obliterated; high frequency content is noted at the initiation of systole. As the lesion becomes more severe the audiofrequency content extends over a longer portion of systole	
	3) The 1st and 2nd heart sounds are obliterated; high frequency content is observed throughout systole and extends partially into diastole. As the lesion becomes more obstructive the audiofrequency content extends over a longer portion of diastole	
	4) When the lesion becomes severe enough to significantly reduce blood velocity, turbulence is also reduced, and the abnormal audiofrequency content is lost. In this case the CPA tracings may be normal. In some patients the heart sound amplitude is reduced.	



Quite an operation

When it comes down to it, any operation can only be rated successful if it produces the required result. And tying up the loose ends is important at the end. Thats why Key Med's operation maintains a veritable army of specialists—a skilled task force of experts, disciplined not only to meet the needs of today, but to anticipate and deal with the challenges of the 80's. To ensure that you receive a complete package of products and services, calculated to meet any eventuality.

But we also believe in after-sales service and problem solving. The best briefing in the world can hit snags when practice replaces theory. We are reactors in every sense of the word. And the main link in our chain is to be on-call when required. Which, we're happy to report, isn't often! Key Med is geared up to produce confidence at the outset, and success at completion. A value for money operation you should know more about.

over surgical lysis alone. Ideally, any substance tested should totally prevent adhesions. Reduction in the number of adhesions or their length of attachment is probably not significant since it is apparent from clinical experience that a single band adhesion can be just as troublesome in terms of intestinal obstruction and strangulation as numerous smaller adhesions.

The experimental model was deliberately designed so that no attempt was made to prevent adhesions at the initial laparotomy. As Ellis (1971) has stated, adhesions are vascular grafts to areas of doubtful viability and it is uncertain whether we should aim to prevent adhesions after a first laparotomy. Where we should aim to prevent adhesions is in the patient undergoing a second or subsequent laparotomy for intestinal obstruction due to adhesions where the bowel is viable and where, after dividing the adhesions, we seek to prevent them reforming.

Sutured peritoneal defects have been shown to act as an adhesive stimulus (Ellis, 1962; Gilmore and Reid, 1976), but in this study adhesions formed to the defect in only about one-third of animals compared with all animals as reported by Gilmore and Reid (1976). This may relate to the fact that the defect was sutured with catgut rather than silk as in the study of Gilmore and Reid (1976). It should, however, be noted that more adhesions formed to the sutured defect in the left flank than to the unsutured defect in the right flank following the initial laparotomy, thus confirming the work of Ellis (1962) who showed that sutured peritoneal defects acted as a stimulus to adhesion formation. Also, in contrast to Gilmore and Reid's study (1976), no reduction in adhesion formation was found with noxythiolin and also the mortality rate was high.

Noxythiolin is manufactured in two forms: Noxyflex which contains 10 mg of amethocaine in each 2·5 g of noxythiolin and Noxyflex S which contains no amethocaine. After breaking the code it was found that all except one animal in the Noxyflex group died and also 8 of those in the Noxyflex S group. Tolhurst Cleaver et al. (1974) reported 100 per cent mortality in a group of rats with faecal peritonitis treated with Noxyflex. No satisfactory explanation could be found for this at the time, but recently it has become apparent that the amethocaine contained in Noxyflex may be toxic to rats. The convulsant dose given intravenously to rats is 1·5 mg/kg body weight (Edwards, 1978). The volume of solution given to the rats, i.e. 2·5 ml, contains 0·25 mg, giving a dose of approximately 1 mg/kg given intraperitoneally. Further ether may raise the toxicity of amethocaine up to tenfold and ether was used to induce anaesthesia and therefore could have taken the dose of amethocaine past the convulsant dose to the lethal dose. Although this provides a satisfactory explanation for those animals treated with Noxyflex, it does not explain the 40 per cent mortality in the animals treated with Noxyflex S which does not contain amethocaine. It must therefore be assumed that noxythiolin in the concentration used is absorbed rapidly through the large areas of peritoneal defect and is toxic to rats. The discrepancy between these results and those of Gilmore and Reid (1976) who had no mortality may be due to the fact that they used a sutured wound only to stimulate adhesions and there were no large raw areas of peritoneum such as those

Table I: SURGICAL LYSIS ALONE

Site of adhesion	No. animals with adhesions Initial laparotomy ($n = 20$)	 After lysis ($n = 20$)

in the present study through which noxythiolin may be rapidly absorbed. Also Gilmore and Reid (1976) used only 1 per cent noxythiolin, compared with 2·5 per cent in the present study.

Animals treated with aprotinin showed no reduction in adhesion formation compared with surgical lysis alone. This does not support the work of Vorster (1968) and Grundmann (1969) who showed that adhesions produced by peritoneal abrasion and instillation of talc could be reduced by a single intraperitoneal injection of aprotinin. However, it should be noted that in these studies adhesions were not completely abolished (Vorster, 1968), but their area of attachment was reduced (Grundmann, 1969). Certainly there are good theoretical reasons for believing that aprotinin should reduce adhesions since it has been shown to reduce the inflammatory response in peritoneal wounds created by cautery and to 'prevent the development of inflammatory granulation tissue' (Grundmann, 1969). Two recent clinical papers have also suggested that aprotinin reduces adhesions. Mooney (1976) treated 20 patients with intraperitoneal aprotinin and at a 'second look' procedure, i.e. laparotomy or laparoscopy, there was a 'marked reduction' in adhesions in 16 of the patients. However, this was an uncontrolled trial. More recently, Perovic et al. (1978) have compared a single dose of intraperitoneal aprotinin with no such treatment in perforated appendicitis in children. The presence of adhesions was indirectly assessed by comparing the incidence of 'mechanical ileus' in the two groups. It was significantly higher in the untreated group. However, the absence of 'mechanical ileus' does not necessarily prove absence of intraperitoneal adhesions.

The results obtained in the experimental model certainly do not support the claims that a single intraperitoneal dose of either noxythiolin or aprotinin prevents adhesions.

Acknowledgements

I wish to thank Professor I. E. Gillespie for his encouragement and critical reading of the manuscript, Miss Linda Hunt for the statistical analysis, Mrs Anne Tomlin for technical assistance and Mrs Marilyn McNiven for typing the manuscript.

A safe and effective disposable low pressure suction drain

M. F. SEELY, W. A. HYDE AND MILES IRVING*

SUMMARY

The physical and microbiological properties of a new disposable suction drainage system have been investigated under clinical and laboratory conditions. The system appears to have overcome the disadvantages associated with previous disposable and reusable low pressure suction drainage systems for use after surgical operation in that this system effectively prevents reflux and retrograde contamination.

SUCTION drainage systems are widely used in surgical practice to remove blood and secretions that might otherwise lead to haematoma or seroma formation with possible infection and delay in healing. Such drains may be left in position for several days, their effectiveness being maintained by repeated charging of the vacuum.

We have examined the physical and microbiological properties of a disposable system (DreVac Drain, Astra-Sjuco AB, Sweden) which claims to have incorporated mechanisms that effectively prevent the danger of retrograde contamination during the maintenance of suction and whilst recharging is taking place to see if the claims can be substantiated.

The Drevac system

The system (*Fig.* 1) consists of a fine plastic cannula with multiple perforations at one end which is laid into the site to be drained, the other end attached to a trocar being brought to the exterior through the body wall. The cannula is attached to the inlet tube of the bellows. The tube can be occluded by a clamp to isolate the bellows during recharging. The inlet tube within the bellows is protected by a plastic flap valve which prevents reflux during charging (*Fig.* 2). An outlet tube from the bellows, which can also be occluded by a clamp, leads into a plastic drainage bag where it is similarly protected by a flap valve to prevent reflux. The air outlet from the drainage bag is protected by a synthetic foam plug.

Charging of the system is accomplished by occluding the inlet tube, opening the outlet clamp and squeezing the bellows, following which the outlet clamp is closed and the inlet clamp opened. The bellows are rather difficult to compress and never empty completely, but this does not interfere with effective functioning.

Studies

Loss of vacuum

The loss of vacuum over a period of 12 h in the completely sealed bellows was studied in eight systems by connecting the inlet tube of the bellows to a manometer consisting of a glass tube standing in a conical flask containing mercury. The bellows were then evacuated and the column height obtained was measured at zero time and every 30 min for the first hour and then hourly thereafter to the end of the 12 h period. The study was repeated 5 days later after eleven rechargings to see whether the initial physical properties had changed.

Reflux from the bellows into the inlet tube was studied in eight systems by sucking up water into the bellows and then trying to evacuate the bellows manually with the outlet tube clamped and the inlet tube unclamped. The water contained methylene blue for easy visualization of any reflux.

Bacteriological studies

Four bacteriological studies of the system were undertaken.

1. Whole systems were removed from 33 patients in whom they had been used and the bacteriological state of the suction catheter, the bellows and the drainage bag were all determined. Particular note was made of whether bacteria present in the drainage bag could be grown from the bellows and catheter.
2. Six systems were set up in the surgical wards with the drainage cannulas inserted through the rubber diaphragm of a sterile glass blood bottle containing a clear culture medium (thioglycollate USP haemin and menadione LAB-M). The system was repeatedly charged at 12-hourly intervals over a 5-day period, on each occasion the bellows being allowed to suck in 30 ml of culture medium. Three of the systems were then isolated by occluding the inlet clip and three were left without suction throughout the study. To allow easy suction of the system a no. 17 BWG needle with a 13-mm Millipore 0·23 μm bacterial filter was inserted through the diaphragm to allow equalization of pressure.
3. As the only possible point of outside contamination of the system is through the air filter in the drainage bag, the study was repeated with constant moistening of the air filter with the culture medium such as might occur if a patient compressed the bag by lying on it.
4. Experiment 3 above was repeated in the laboratory, but on this occasion the air filter into the drainage bag was fitted with a 0·23 μm Millipore filter. The drainage bags were then contaminated with *Pseudomonas aeruginosa* and the system then studied in the same way for a further 5 days.

All specimens from the above experiments were collected in a laminar flow filtered exhaust station, the drains being swabbed with 70 per cent isopropyl alcohol before the contents were withdrawn with sterile syringes and cultured aerobically and anaerobically.

Bacterial growth was classified depending upon the number of colonies:

$>300\times10^2$/ml	+++
$>150<300\times10^2$/ml	++
$>50<150\times10^2$/ml	+
$1<50\times10^2$/ml	±

Organisms were identified by conventional laboratory methods.

Results

Loss of vacuum

The loss of vacuum in the bellows after occlusion of the inlet tube is shown in *Fig.* 3. An initial rapid fall-off in suction pressure of 20 mmHg in the first hour is followed by a period of stabilization over the next 11 h to a level between 100 and 110 mmHg. After 5 days and eleven evacuations the maximum vacuum that could be obtained was only some 10 mmHg less than that obtainable on the first day, and at 12 h the vacuum measured was no different from that on the first day.

Reflux

In none of the eight systems tested could reflux up the unoccluded inlet tube be obtained by compression of the bellows.

Bacteriological studies

Organisms were isolated from 7 of the 33 systems removed from patients. Bacteria were present in all three compartments of 5 of the systems studied which had all come from patients with intraperitoneal infections. From 1 of these 5 systems, and from the other 2 systems, organisms were isolated from the drainage bags which could not be isolated from either the bellows or inlet in spite of enrichment techniques (*Table I*). These were presumed to be environmental contaminants.

Six of the 33 systems investigated were found to have had their air filters accidentally moistened by the contents of the drainage bags. The three instances of contamination in the drainage bags came from this group.

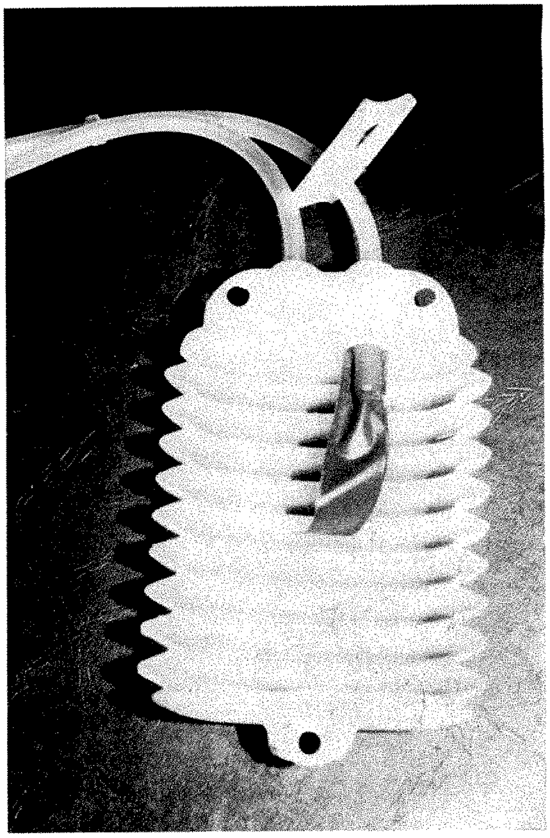

Fig. 2. View of non-return valve in the cut-open bellows.

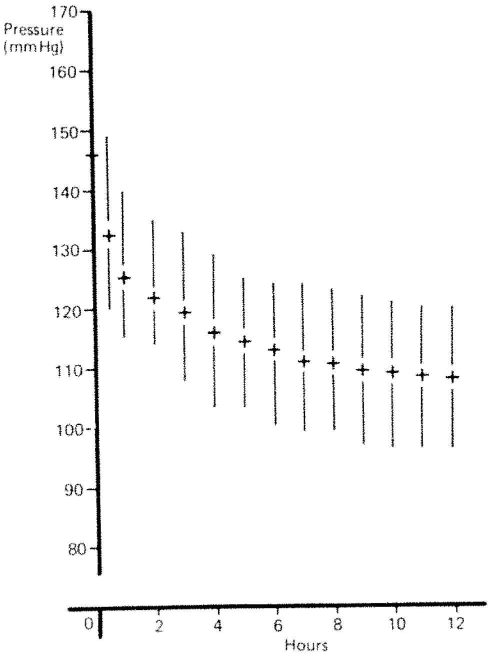

Fig. 3. Loss of vacuum in the bellows measured over a period of 12 h in eight systems (mean ± s.d.).

The experiments conducted in the ward showed that the whole system remained sterile in the wards provided that the drainage bag inlet filter was not contaminated. Of the 6 systems where the inlet filter was deliberately moistened with culture medium, 4 showed contamination of the culture medium in the drainage bags by the fifth day with three species of organism. However, in no instance did retrograde contamination from the drainage bags to the bellows or reservoir occur.

In the studies in which the drainage bag was contaminated with pseudomonas no spread to the bellows or reservoir occurred throughout the 5 days.

Discussion

The main concern always expressed about surgical drains has been the danger of migration of microorganisms by retrograde spread down into the cavities being drained. In the case of suction drainage systems these fears are compounded by the possibility of reflux into the drained area during recharging or accidental compression of the container. It was such an occurrence that according to Wyatt (1969) led to two severe wound infections following cholecystectomy and prostatectomy.

A detailed study of disposable and reusable drainage systems by Lumley et al. (1974) showed that both types were subject to spontaneous loss of vacuum and that positional change of the container of the magnitude encountered in clinical practice could esaily produce reversal of flow from the container into the wound.

Their study also showed that in laboratory conditions designed to simulate the clinical situation, bacterial contamination could occur in both systems, but was more likely in the disposable rather than the reusable systems.

The main requirements of an effective low pressure suction drainage system should be maintenance of suction without the need for frequent recharging and the incorporation of mechanisms that effectively prevent reflux and retrograde bacterial contamination.

The DreVac system would appear on the basis of our investigations to have achieved this aim. Its ability to maintain low pressure suction after repeated compression over several days compares favourably with the other disposable systems described by Lumley et al. (1974). The risk of reflux and retrograde contamination even by an organism such as *Pseudomonas aeruginosa*, which is motile at room temperature, appears to have been eliminated by the use of the flap valve and occlusive clips reinforced by the fact that the whole system is a closed one. Indeed, even when contamination of the drainage bags occurred either unintentionally or deliberately, as in the laboratory studies, no retrograde contamination of the bellows or culture medium reservoir could be detected. Our studies demonstrate that even contamination of the drainage bag can be prevented by the fitting of a Millipore filter to the air inlet.

Some authorities have counselled against the use of drainage after splenectomy because of the danger of subphrenic abscess formation. We have used this system in over 70 splenectomies in the past 3 years without complication.

It would appear that, apart from some difficulty in physically compressing the bellows, the DreVac disposable drain satisfies the mechanical and bacteriological properties necessary for a safe, effective low pressure suction drainage system.

Duct ectasia in the male

R. E. MANSEL AND W. P. MORGAN*

SUMMARY

Three cases of inflammatory duct ectasia occurring in the male breast are described. The clinical presentation of the disease in the male closely resembles that in the female. Nipple retraction, nipple discharge, periareolar inflammation and bilateral involvement are all seen. Conservative measures produced unsatisfactory results similar to those in women. A similar operative approach to that used in women is advocated.

INGIER (1909) first drew attention to the association of inflammation with mammary duct ectasia and his findings have been confirmed by several authors (Adair, 1933; Bonser et al., 1961; Walker and Sandison, 1964; Haagensen, 1971). None of these authors has reported a similar condition in the male breast, although the histological picture of periductal mastitis has been described in a male by Tedeschi and McCarthy (1974).

Case reports

Case 1: J. C., aged 62 years, presented in October 1976 with a 4-week history of a painful red lump in the left breast associated with an intermittent bloody nipple discharge. He had noticed increasing bilateral painless nipple retraction over the previous 2 years. His past history included a transurethral prostatectomy one year previously for benign hypertrophy and neurological investigation in 1970 for recurrent headaches. Air encephalography showed slightly dilated lateral ventricles and a diagnosis of arrested hydrocephalus was made.

Examination in October 1976 showed a 5 × 5 cm red, tender, non-fluctuant mass lying deep to the left areola. Both nipples were deeply retracted. Mammograms were reported as showing bilateral gynaecomastia, greater on the left side. The redness and tenderness disappeared spontaneously over the next 2 weeks, but the inflammation returned 1 month later and in December 1976 the patient was admitted for drainage of an abscess in the left breast. The pus gave a growth of *Staphylococcus aureus* and *Staphylococcus albus* on culture. The wound healed after several days' drainage, but the inflammatory process recurred 2 weeks later. The breast was now diffusely indurated and oedematous and a central mass 3·5 × 3 cm was palpable beneath the partially retracted nipple (*Fig*. 1).

At operation the left breast and terminal lactiferous ducts were removed by an extended total ductal excision operation as developed by Urban and Adair (Hadfield, 1960) and the wound was packed with acroflavine gauze. Histology showed extensive chronic inflammation and fibrosis with granulation tissue (*Fig*. 2). The wound was dressed with a silicone elastomer stent (Wood et al., 1977) and healed up over the next month.

The patient remained well for the next 5 months but in June 1977 he again presented as an emergency with a 4-day history of pain in the other breast. On examination he was found to have a subareolar abscess in the right breast and this was drained under general anaesthetic. *Bacteroides fragilis* was subsequently cultured from the pus obtained. The wound healed over the next month but pain and induration persisted under the areola and total ductal excision was carried out in September 1977 using a subareolar incision. The breast tissue, which mainly consisted of dense fibrotic bands, was completely removed after freeing the lactiferous ducts from the base of the nipple. This procedure allowed the retracted nipple to evert normally and the wound was closed with suction drainage. Histological examination of the specimen showed chronic stromal inflammation and a mild degree of ductal proliferation which was accompanied by periductal inflammation. A wound swab taken at operation grew *S. albus*, *S. aureus* and a non-haemolytic streptococcus. The wound healed uneventfully (*Fig*. 3). The patient has had no further trouble on either side.

Case 2: J. L., aged 47 years, presented in June 1973 with a 12-year history of recurrent abscesses in the right breast. On previous occasions the abscess had discharged spontaneously through a small periareolar sinus. There was no history of diabetes mellitus. On examination a small abscess was noted beneath the right nipple which appeared to be otherwise normal. The abscess was incised and packed after evacuating some thick pus, which was sterile on culture. The wound healed satisfactorily and the patient was discharged from the out-patient clinic. However, he was admitted again as an emergency in February 1976 with a recurrent abscess draining through a small sinus on the medial edge of the areola. The patient reported that abscess formation had occurred two or three times since the first operation. Incision drainage and packing were again carried out with evacuation of thick pus which grew *Escherichia coli*. The patient was discharged with a healed wound in March 1976.

Eleven months later he was referred to outpatients with a recurrence of the discharging sinus medial to the right nipple, but without abscess formation. At operation in March 1977 the sinus and a block of underlying breast tissue were excised with primary wound closure under antibiotic cover. Histological examination showed large areas of chronic inflammation with marked focal granulomatous reaction. The wound healed satisfactorily and the patient was discharged, only to reappear in 8 months time with another sinus medial to the right nipple. At this stage it was felt that a radical excision was necessary to clear all diseased tissue. The patient expressed a preference for the certainty of a conservative simple mastectomy to a ductal excision procedure and this was carried out in November 1977. Postoperative healing was uneventful and the patient has remained free of inflammation since the operation.

Case 3: W. G., aged 52 years, presented in April 1978 with an 8-week history of a tender lump in the left breast. This had been treated with antibiotics by his family practitioner. He had then spontaneously developed an intermittent discharge from a sinus situated at 9 o'clock on the left areolar margin (*Fig*. 4). There were no associated problems apart from chronic bronchitis (he smoked 99 g of tobacco per week) and the patient had been taking no other medication. Culture of the discharge was sterile.

At operation 2 weeks later a probe could be passed through the sinus and it ran under the areola to the nipple. It was possible to carry out a subcutaneous mastectomy with excision of the terminal ducts through a circumareolar incision. This included all the tissue surrounding the probe. The wound was closed primarily with sutures and suction drainage. The patient made an uneventful postoperative recovery.

Histology of the excised specimen showed the skin surrounding the fistulous opening to have dense fibrous tissue in the dermis with granulation tissue, containing a mixture of chronic inflammatory and occasional multinucleate giant cells. No acid-fast bacilli were seen. The excised breast tissue contained only one rather distorted duct.

Discussion

Female mammary duct ectasia with associated periductal mastitis, juxta-areola abscess formation and, in a proportion of cases, fistula formation is a

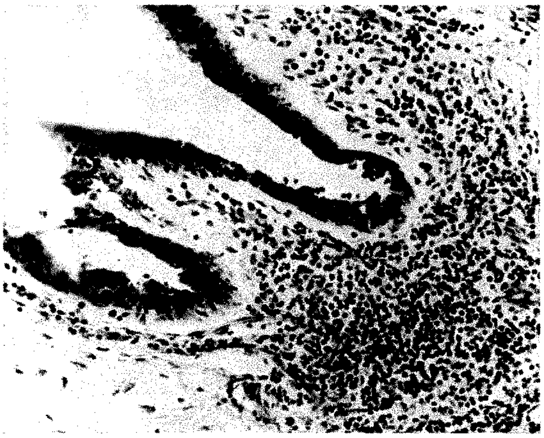

Fig. 2. *Case* 1. Histological section demonstrating chronic inflammatory infiltrate surrounding the breast duct. (HE. × 16.)

well-documented condition (Haagensen, 1971; Walker and Sandison, 1964).

Walker and Sandison have described four clinical types of presentation of duct ectasia in the female:

1. Nipple discharge from a clinically normal breast.
2. A soft irregular mass with an indefinite edge, present in or near the subareolar region.
3. A tender inflamed lump in the juxta-areolar area leading to sterile abscess formation. A simple incision leads to super-added infection with recurrent abscess and fistula formation.
4. A variably tender, craggy, hard mass with irregular edges, sometimes attached to skin and of recent onset.

All three of our male cases presented with juxta-areolar abscess formation, as in Walker and Sandison's group 3. In two of the male cases, simple incision and drainage led to repeated abscess and fistula formation. In the third case, the fistula appeared spontaneously. Other features seen in the male cases which are also seen in the female are the occurrence of bilateral disease, nipple discharge and nipple retraction. Our cases again mirrored the finding in females that pus is commonly sterile in the early stage of the disease but may be invaded with a variety of organisms when fistula formation occurs or on repeated surgical interference.

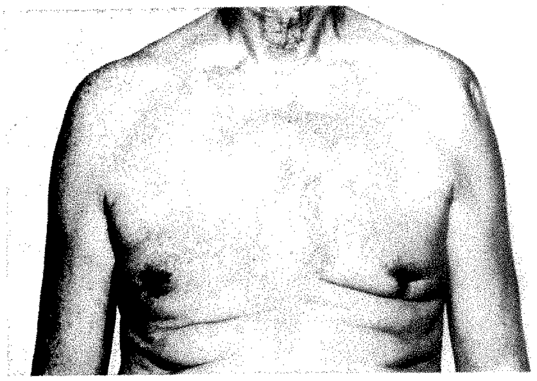

Fig. 3. *Case* 1. Showing the final postoperative appearance.

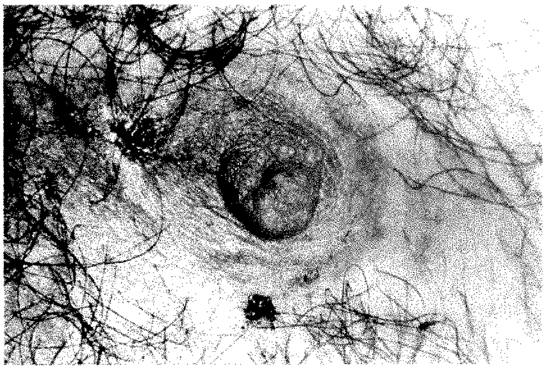

Fig. 4. *Case* 3. The left nipple, showing a sinus at 9 o'clock on the areolar margin.

The traditional view of the pathological events in duct ectasia as described by Haagensen (1971) is that dilatation of the terminal collecting ducts in the sub-areolar zone is the primary event, followed by distension with cellular debris and lipoid material. The duct epithelium atrophies and the lipoid material may extrude into the periductal tissues setting up a granulomatous inflammatory reaction. Finally, post-inflammatory fibrosis leads to ductal shortening and nipple retraction.

However, Dossett (1959) believes that the sequence of events is transposed and chronic periductal inflammation is the primary event. This results in destruction of the elastic network in the duct wall, leading to ductal dilatation. Histology of the excised breast tissue from the male patients presented here shows similar features to those described in the female by Dossett (1959). The predominant picture is that of focal granulomatous infiltration, which was well shown in *Case* 1. Tedeschi and McCarthy (1974) have reported a male with a histological diagnosis of periductal mastitis similar to that in the female, but the clinical presentation was that of a tender juxta-areolar lump. The periductal inflammation, when severe, shows as a density on mammography which is indistinguishable from gynaecomastia, as exemplified by our first case.

Treatment of these inflammatory lesions in the female by simple incision and drainage has been shown to predispose to recurrent fistula formation and this also appears to occur in the male, as shown in two of our case reports.

Curative treatment in the female depends on whether the abscess appears to be derived from single or multiple duct involvement; with the single duct entity treated by fistula excision, as described by Atkins (1955), and the multiple duct type by total duct excision, as described by Hadfield (Hughes, 1977).

The same principles apply presumably to male cases, although the role of the limited operation of fistula excision is uncertain at the present time; it was unsatisfactory in our *Case* 2. In the male, there are no cosmetic or functional considerations to contraindicate a formal duct excision, and this should probably be considered the treatment of choice in all cases.

Acknowledgements

Cases 1 and 2 underwent their definitive management under Professor L. E. Hughes. We are grateful to him for drawing our attention to the concept of duct ectasia in the male and to Mr M. Baum for allowing us to report *Case* 3.

A MAJOR ADVANCE IN ANTIBIOTIC THERAPY

Already used widely in

●serious infections

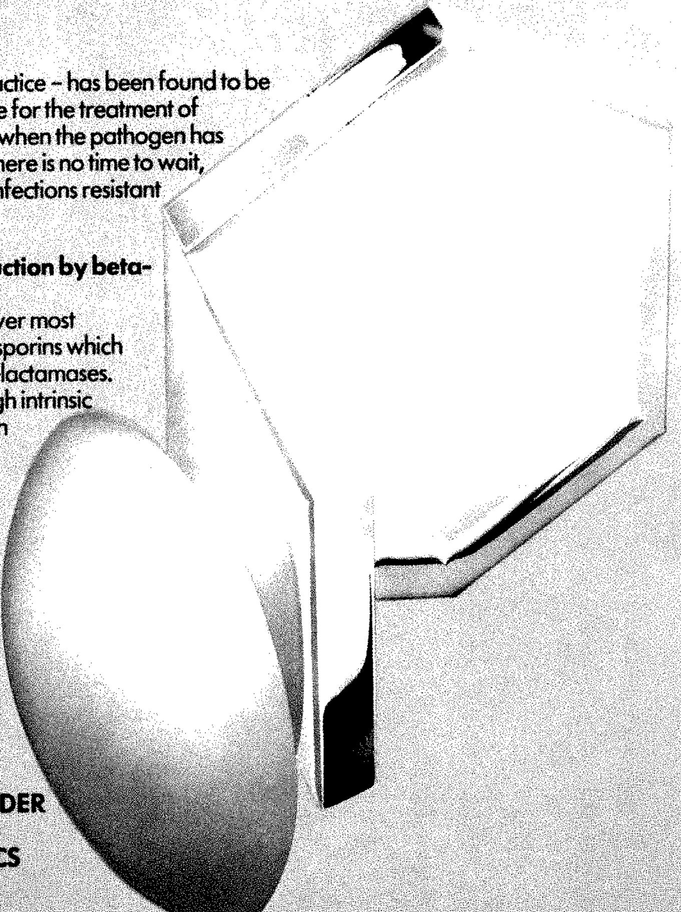
INJECTABLE

ZINACEF

cefuroxime sodium

Zinacef – in hospital practice – has been found to be particularly appropriate for the treatment of serious acute infections when the pathogen has not been isolated and there is no time to wait, and in difficult to treat infections resistant to other antibiotics.

Zinacef resists destruction by beta-lactamases
A distinct advantage over most penicillins and cephalosporins which are destroyed by beta-lactamases. This, together with a high intrinsic activity gives Zinacef an extended clinical spectrum.



Zinacef is effective against:

- **most common pathogens**
- **many uncommon pathogens**
- **multi-antibiotic resistant pathogens**

ZINACEF, A BROADER SPECTRUM THAN MOST ANTIBIOTICS

Prescribing information

Presentation
Vials of 250mg, 750mg and 1·5 grams and infusion pack of 1·5 grams. All containing cefuroxime as cefuroxime sodium.
Indications
Serious bacterial infections, especiall where the organisms have not yet been identified.
Conditions include:
Chest infections
Septicaemia
Soft-tissue infections
Obstetric and gynaecological infections
Bone and joint infections
Ear, nose and throat infections
Meningitis
Gonorrhoea
Dosage
Adults: Generally 750mg t.d.s. i.m. or i.v. Severe infections 1·5 grams t.d.s. i.v. Frequency of injections can be increased to six-hourly if necessary, giving total doses of 3 grams to 6 grams daily.
Infants and Children: 30 to 100mg/kg/ day in three or four divided doses. 60mg/kg/day will be appropriate for most infections.
Neonates: 30 to 100mg/kg/day in two or three divided doses.
Gonorrhoea: Single dose of 1·5 grams (2 x 750mg i.m. into different sites).
Contra-indications
Hypersensitivity to cephalosporins.
Precautions
Cephalosporins may, in general, be given safely to patients who are hypersensitive to penicillins.
As with all drugs, Zinacef should be administered with caution during the early months of pregnancy.
Zinacef does not interfere with enzyme-based tests for glycosuria. Cephalosporins interfere with tests for glycosuria which use copper reduction or ferricyanide methods and with the alkaline picrate assay for creatinine. As with other antibiotics, prolonged use may result in the overgrowth of non-susceptible organisms.
Zinacef should not be mixed in the syringe with aminoglycoside antibiotics.
Reduce dosage when renal function is markedly impaired.
Cephalosporins at high dosage shoul be given with caution to patients receiving concurrent treatment with potent diuretics such as frusemide, as these combinations are suspected of adversely affecting renal function. Clinical experience with Zinacef has shown that this is not likely to be a problem at the recommended dose levels.
Side effects
Adverse reactions are rare and generally mild and transient, e.g. rashes, gastro-intestinal disturbanc candida intertrigo, decreased haemoglobin concentration, eosinophilia, a positive Coombs' test, transient rises in serum liver enzymes and transient pain (after i.m. injection).
Storage
Protect from light.
Product Licence number: 4/0263
Price to Hospital (exclusive of VAT)

5 x 250mg	£0·70 per vial
5 x 750mg	£2·10 per vial
1·5 grams	£4·20

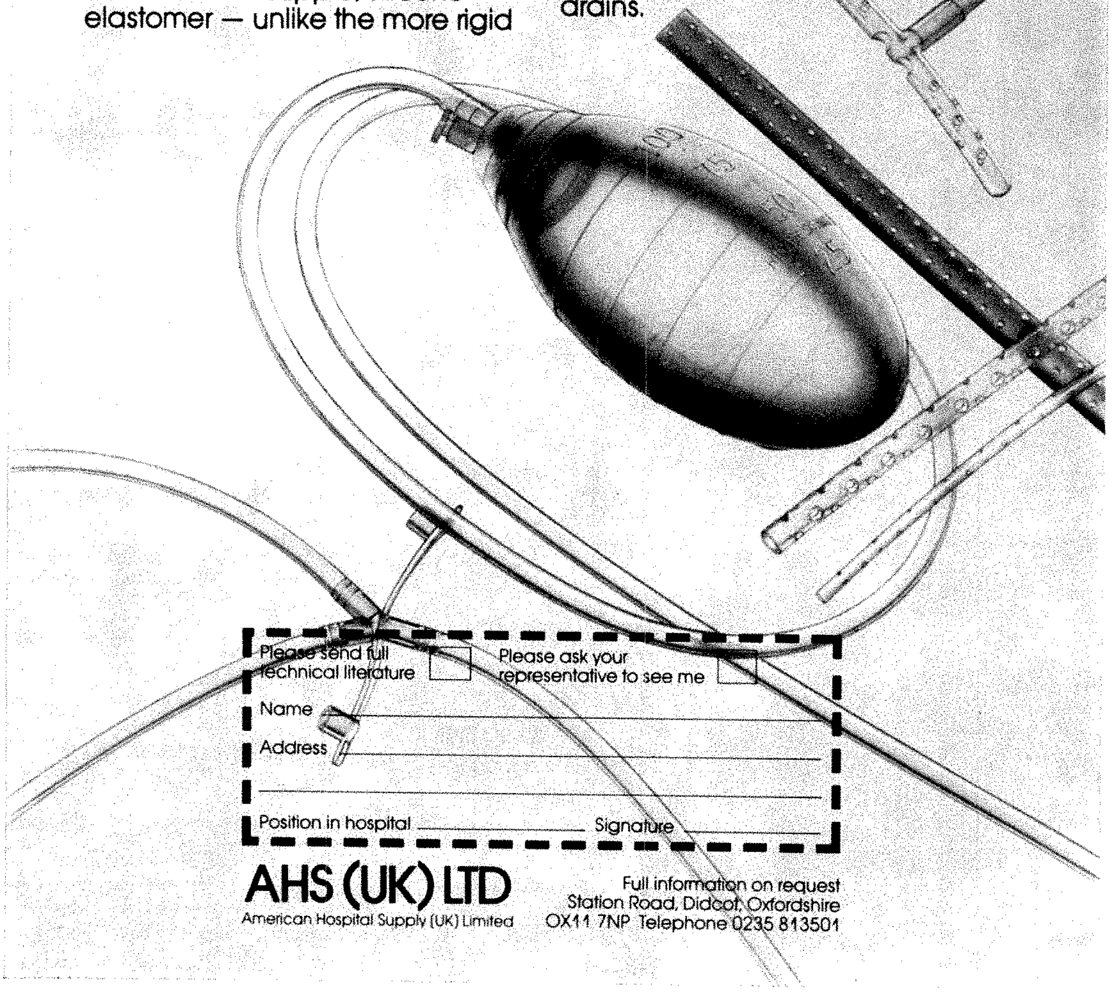
Heyer-Schulte Jackson-Pratt Suction Drain System

Soft and simple

The Jackson-Pratt Drain System has been proven in a wide variety of post-operative drainage procedures.

It's made with supple, silicone elastomer — unlike the more rigid devices that can cause trauma. And, it's available with round and flat suction drains, a T-tube drain and 100cc reservoir for connection to single or multiple drains.



Please send full technical literature ☐ Please ask your representative to see me ☐

Small bowel strictures after blunt abdominal trauma

C. G. MARKS, D. J. NOLAN, J. PIRIS AND C. U. WEBSTER*

SUMMARY

Two patients with strictures of the small intestine after blunt abdominal trauma are reported. In the first there were multiple severe injuries and the ileal stricture due to a mesenteric tear was not diagnosed until 6 weeks later. In the second an apparently minor injury was responsible for direct damage to the wall of the jejunum and a subsequent stricture.

Case reports

Case 1: D. W., a 30-year-old man, was admitted as an emergency on 12 February 1977 following a road traffic accident. His principal injuries were a rupture of the thoracic aorta, a Monteggia fracture of the right forearm and pelvic fractures.

The ruptured aorta was repaired on 14 February (Mr A. J. Gunning), when a virtually complete transection of the aorta, situated 3 cm beyond the origin of the subclavian artery, was replaced by a Dacron graft. Recovery was satisfactory.

Later during this admission it was noted that the patient's abdomen was distended for 5 days, a finding attributed to a paralytic ileus secondary to a retroperitoneal haematoma. He was discharged home on 15 March.

He was readmitted on 26 March (6 weeks after the accident) when he complained of severe, colicky, epigastric and central abdominal pain. He had not vomited and there was no history of bowel upset. On examination he was noted to be dehydrated and in severe pain. His abdomen was distended and there was marked epigastric tenderness.

Plain abdominal X-rays showed distended loops of small bowel and a diagnosis of subacute obstruction or an inflammatory mass was suggested. A small bowel barium infusion was therefore performed, which showed dilatation of the distal jejunum and proximal ileum. In the ileum there was complete hold-up of the contrast medium in front of the sacrum, where a small leak was demonstrated.

A laparotomy followed, when an ischaemic stricture of the ileum, with a sealed-off perforation, was found opposite a mesenteric tear and adherent to a pelvic fracture posteriorly. The stricture was resected and the postoperative course was uneventful. The patient was discharged on 5 April.

He was readmitted, however, on 13 April, when an intraperitoneal abscess was drained. No communication to the bowel was found and this wound was left open; it was noted to have healed completely on 30 June.

The histology of the resected bowel showed ischaemic necrosis of the whole thickness of the bowel wall.

Case 2: B. G., a 33-year-old man, was admitted as an emergency on 16 July 1978 with abdominal pain after being crushed for a few moments between a heavy motor roller and a wall. On examination he was not shocked; the only positive finding was tenderness across the epigastrium and left hypochondrium.

A plain abdominal X-ray showed no abnormality and a diagnosis of bruising of the anterior abdominal wall was made. He was observed for 24 h and sent home.

On 27 July he was seen again, at home, because he was feeling unwell, with loss of appetite. Eight days after his injury he had vomited, following a large meal, and subsequently had been unable to eat a full meal.

On examination he was tender across the lower third of the left rectus but there were no other abnormalities. He was given a bland diet. His symptoms improved but he still found that he was unable to eat a large meal without nausea and central abdominal pain. A barium meal was requested and showed a segment of narrowing in the proximal jejunum, which was confirmed by a small bowel barium infusion on 18 August.

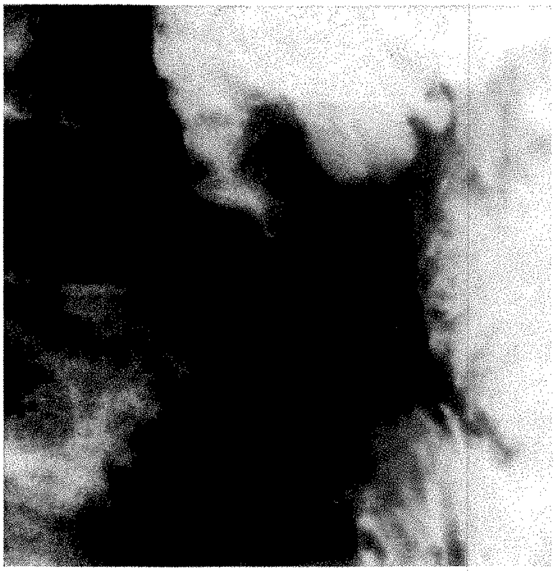

Fig. 1. A small bowel barium infusion showing a close-up of the jejunal stricture on an oblique spot view.

He continued to lose weight and a further small bowel infusion on 2 October (*Fig.* 1) showed that the bowel proximal to the stricture was more dilated. He was readmitted on 20 October.

A laparotomy was carried out, when a stricture in the jejunum, 1 m from the duodenojejunal flexure, was found wrapped in omentum. There was no evidence of perforation or a mesenteric tear. The stricture was resected and the patient made a satisfactory recovery, returning home on 29 October.

The histology of the stricture showed ischaemic damage to the outer coat affecting mainly the circular muscle with sparing of the submucosa and mucosa. However, these layers were infolded secondary to the fibrosis and contraction of the underlying muscle and thereby contributed to the obstruction.

Discussion

Strictures of the small intestine due to blunt trauma appear to be very rare (Marston, 1977). There was only one such stricture in a series of 95 benign strictures reported from Stockholm over a 12-year period up to 1968 (Räf, 1969). In 1967 Gillet et al. reported a stricture in a child aged 6 similar to that in our second patient. In a review of the literature these authors found 48 reports of post-traumatic stricture described since 1901. Two types of stricture were recognized, one due to direct trauma to the bowel wall and the other secondary to a mesenteric tear. The strictures were confined to the proximal and distal extremes of the small bowel where the bowel was relatively fixed—the proximal jejunum and terminal ileum. The mechanism of injury was thought to be shearing or tearing of the mesentery at the points

---

* Departments of Surgery, Radiology and Pathology, Radcliffe Infirmary, Oxford.

of fixation. In addition, it has been suggested that these segments of small bowel are particularly liable to be crushed against the spine. Both the strictures presented here were close to the midline and in front of the spine.

A subserosal haematoma associated with the use of the lap-type seat belts (Tolins, 1964; Di Fiore and Gin, 1968) is one example of delayed presentation but there may be a long interval of up to several months or even years between the injury and the onset of symptoms. The symptoms may be acute, with complete obstruction or even perforation, as illustrated by our first patient, or chronic with abdominal pain and distension due to incomplete obstruction, as in our second patient. Where the possibility of a traumatic stricture is considered a small bowel barium infusion (Sellink, 1976; Nolan and Pantelidis, 1978) will usually demonstrate the stricture. This investigation helped in the management of both our patients and led to the correct preoperative diagnosis.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Total small bowel strangulation: a case report

GÖSTA PETTERSSON, JAN-OLOV SVENSSON AND NILS DARLE*

SUMMARY

A case of strangulation of the entire small intestine caused by an internal incarcerated hernia is presented. At laparotomy the small intestine was severely discoloured, paralytic and the viability of the bowel was questionable. No resection was performed. At a second laparotomy 10 h later the intestine was hyperaemic and exhibited lively motor activity. Recovery was complete. The importance of prolonged conservative management in avoiding extensive resection is stressed.

MASSIVE small bowel resection produces profound metabolic deficits but adequate nutrition is maintained unless the resection exceeds 50 per cent of the small bowel length (Koeberle, 1881; Haymond, 1935; Bothe et al., 1954) or a major portion of the ileum is resected (Booth, 1961). Preservation of the distal ileum and the ileocaecal valve prolongs the intestinal transit time and improves the absorption (Kalser et al., 1958). Early laparotomy is of great importance in patients suffering from mesenteric vascular occlusion or strangulating obstruction but at laparotomy it is sometimes difficult to determine the viability of the bowel and to define the limits of the segment to be resected.

Case report

A 36-year-old woman, who had previously undergone cholecystectomy and appendicectomy, was admitted to Sahlgrenska Sjukhuset, Göteborg, with a history of severe abdominal pain, starting in the right lower part of the abdomen 11 h earlier. She had been vomiting repeatedly and had had continuous pain. On admission the abdomen was distended and diffusely tender but there was no rigidity. A plain X-ray of the abdomen was normal. On examination 3 h later the patient was in great pain, pale and feverish. Her pulse was weak and rapid and her blood pressure was not measurable. The abdomen was distended and there was generalized tenderness with guarding.

At laparotomy, 16 h after onset of symptoms, the peritoneal cavity contained 500 ml of foul-smelling, turbid fluid. The small bowel was dilated and severely discoloured. The entire small bowel, with the exception of 15 cm proximally and 10 cm distally, was found to be rotated and strangulated by a loop of small bowel incarcerated through a hole in the mesentery at the ileocaecal angle (*Fig.* 1). The small bowel mesentery had a short base and the caecum was mobile, making rotation possible. The incarcerated loop was reduced and the intestine freed. As soon as the herniated loop was reduced and the mesentery untwisted a pulse could be felt in the mesentery. The bowel was totally paralytic, however, and did not react to mechanical stimulation. After 2 h the bowel was still blackish but some parts did react weakly to mechanical stimulation. The viability of the entire affected bowel was doubtful. Any excision would have been extensive and we therefore decided not to resect but to perform a second laparotomy later.

The first few postoperative hours were dramatic. The patient's circulation was very unstable, and in spite of intensive fluid replacement (about 1000 ml/h) she tended to go into hypovolaemic shock. The second laparotomy was carried out after 10 h. The peritoneal cavity now contained 2000 ml of odourless serosanguineous fluid. The bowel was purple–red, hyperaemic and exhibited very lively spontaneous motor activity (*Fig.* 2).

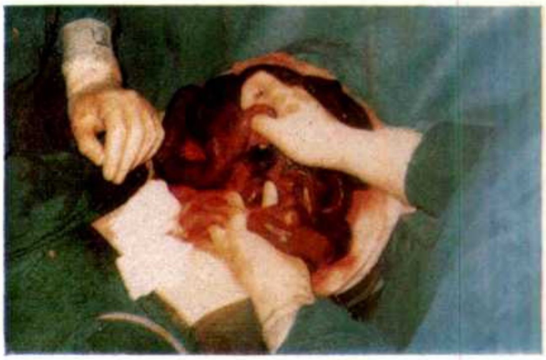

Fig. 1. The small bowel after the reduction of the strangulation. The assistant is holding two fingers through the hole in the mesentery.

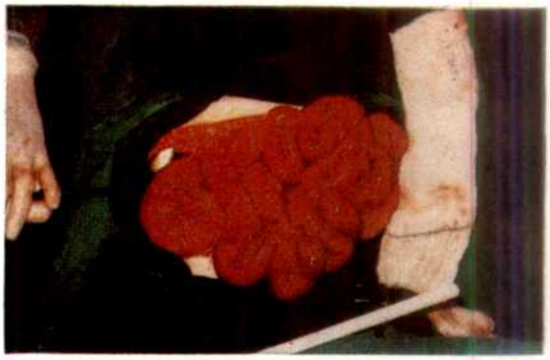

Fig. 2. The hyperaemic small bowel at the second laparotomy.

After the second laparotomy the patient's condition improved steadily. Altogether the patient was given 14 l of fluid during the first 24 h, including 2 units of blood, 1000 ml of Dextran 40, 500 ml of Dextran 70 and 4500 ml of plasma. The external losses measured during the same period were 7·8 l. The volumes of the losses and the fluid therapy decreased to normal values after 5 days. Oral fluid was started on the eighth day and parenteral nutrition was stopped on the eleventh day. Peritoneal lavage (totalling 13 l) was given during the first 3 days. Antibiotics (gentamicin and benzylpenicillin) were started at the primary operation and continued for 8 days. One dose of steroid (methylprednisolone 2 g i.v.) was given during the first operation.

Bowel motions started on the fifth day, with loose bloody stools containing tissue debris that may have been necrotic mucosa. The blood ceased after a week. During the period of hospital stay the number of stools decreased from 6–8 per day to 3–5 per day. The patient complained of postprandial abdominal pain.

A barium meal was performed on the eighth postoperative day. The passage was slow and barium reached the caecum in 16 h. The proximal part of the small bowel was slightly dilated with a normal mucosal relief pattern. The middle and distal parts showed severe changes, with a narrow, rigid lumen lacking the normal mucosal pattern. The changes resembled extensive, advanced Crohn's disease. A second barium meal on the eighteenth day showed a radiological improvement. A third barium meal after 3 months was normal.

---

* Department of Surgery I and III, Sahlgrenska Sjukhuset, University of Göteborg, S-413 45 Göteborg, Sweden.

The patient was discharged from the hospital after 3 weeks. Within 2 months the stools were normal, with 1–2 motions a day, and the patient had regained her preoperative weight. After 4 months she was readmitted and operated upon for obstruction due to an adhesion. At this laparotomy the small bowel looked normal.

Discussion

Internal herniation is an uncommon cause of bowel obstruction. In this case it was combined with rotation of the whole small intestine and the caecum with strangulation of almost the entire small intestine. At operation there was peritonitis and most of the small bowel gave the impression of gangrene but there were still signs of viability, with pulsations in the mesentery and a weak reaction to mechanical stimulation in some parts of the affected bowel.

Any sign of viability was sufficient reason for not resecting since the unaffected small bowel was very short. Second laparotomy has previously been recommended after reconstructive vascular surgery on the superior mesenteric artery (Shaw and Magnard, 1958; Glotzer and Glotzer, 1966). After total occlusion of the superior mesenteric artery in dogs perforation may occur after 9–10 h (Marston, 1977). Less than 10 h between the first and the second laparotomy probably would have been long enough for exclusion of an irreversible infarction.

The consequences of intestinal strangulation are blood and plasma trapping, release of vasoactive substances and bacterial invasion of the wall of the gut. As long ago as 1934, Holt demonstrated the protective effect of saline transfusion following strangulation of the bowel. From animal experiments it is well known that revascularization of an ischaemic bowel is clearly unsafe, with increasing mortality, depending upon the duration of ischaemia (cf. Marston, 1977). Again, the protective effect of fluid therapy has been demonstrated (Marston, 1963; Chiu et al., 1972). The present case clearly illustrates the central role of fluid therapy in this condition. To maintain the balance we had to give about twice the measured volume of external losses. Milliken et al. (1965) reduced the mortality from revascularization in animal experiments by reducing endotoxin production. The antibiotics, the peritioneal lavage and the steroids might have contributed to our success. The benefit of low molecular weight dextran and other plasma substitutes in the treatment of intestinal shock has been studied by Dawidson et al. (1978).

Randomized prospective matched pair study comparing peritoneovenous shunt and conventional therapy in massive ascites

SIMON WAPNICK, SAUL J. GROSBERG AND MARK I. EVANS*

SUMMARY

A prospective randomized matched pair study was designed to test the efficacy of the peritoneovenous (LeVeen) shunt as a treatment for massive cirrhotic ascites compared with traditional medical therapy. Patients who failed to lose weight while on a low salt diet and fluids restricted to 1000 ml daily were placed in the study group. Weight loss, decrease in abdominal girth and diuresis were significantly greater ($P<0\cdot01$) for surgical patients than for their medically treated counterparts. The surgical technique is simple, quick and inexpensive. The surgical patients outlived their matched partners in 12 of 14 pairs where a definitive comparison was possible ($P<0\cdot02$). The median stay in hospital after randomization was shortened from 32 days with medical therapy to 15 days for those undergoing the shunt operation. Those treated medically experienced a significant rise in mean blood urea nitrogen and K^+ ($P<0\cdot02$). Patients with alcoholic hepatitis, hyperbilirubinaemia (bilirubin >154 μmol/l), peritoneal sepsis, severe coagulopathy and those who had recently bled from oesophageal varices are poor risks for the surgical procedure.

THE onset of ascites in cirrhosis is a critical turning point in the course of hepatic decompensation. Medical management is based on salt and water restriction and diuretic therapy. Overutilization of diuretics may deplete the intravascular fluid compartment and precipitate functional renal failure. Oliguria, azotaemia or stubborn resistance to drug therapy herald a poor prognosis (Garceau and Chalmers, 1963; Conn, 1973). Insertion of the LeVeen peritoneovenous shunt in such patients has been shown to overcome refractory ascites and even reverse the hepatorenal syndrome (LeVeen et al., 1976; Reinhardt and Stanley, 1977; Wapnick et al., 1977, 1978; Grosberg and Wapnick, 1978).

A randomized prospective matched pair study was designed to compare the LeVeen shunt with conventional therapy in patients with cirrhotic ascites. The present manuscript describes the results of this trial conducted over a 2-year period.

Patients and methods

Between July 1975 and June 1977, cirrhotic patients admitted to the Gastrointestinal Medical Service of the Brooklyn Veterans Administration Hospital with ascites were placed initially on a diet containing 500 mg of sodium with water limited to 1000 ml per day. The age, duration of illness and associated medical diseases were recorded. Daily weights, measurement of abdominal girth and twice-weekly estimation of blood urea nitrogen, serum creatinine, electrolytes, bilirubin, liver function tests, urine flow, urine creatinine and Na^+ were determined. Progress was reviewed after 14 days. If the ascites and body weight had not decreased, and oliguria persisted, the patient was randomly entered into the prospective study unless the patient refused or a specific complication precluded one or other of the treatment protocols.

Patients with known peritoneal or systemic infection, congestive heart failure, primary renal disease or recent evidence of variceal bleeding were excluded. Cirrhotics in stage III or IV hepatic encephalopathy or jaundice (bilirubin >154 μmol/l) were also excluded. However, if liver function or mental status improved, such patients were entered into the study if massive ascites persisted or the hepatorenal syndrome supervened.

Patients were stratified into three groups according to the highest serum bilirubin level on the current admission (*Table I*). The patients were further divided into a high creatinine (>177 μmol/l) and low creatinine group. Randomization to either medical or surgical therapy for patients was then achieved on the same day by pulling a number from an envelope. Patients in the medical group were matched with those in the surgical group according to the subgroups listed in *Table I* and sequentially according to the date of entry into the study. This study was approved by the Human Studies Committee of the Brooklyn Veterans Administration Hospital. Each patient agreed to both forms of therapy before entering the study. Thirty-four patients were entered into the study and all completed the randomly assigned therapy.

Medical therapy

The sequential dose and type of diuretic therapy are shown in *Table II*. Diuretic therapy was withheld if azotaemia (BUN > 5 mmol/l) was present. Frusemide (furosemide) was administered if hyperkalaemia (serum K>5 mmol/l) was present or if the patient had become refractory to the diuretics listed in *Table II*.

Table I: STRATIFICATION IN RANDOMIZED STUDY

Group	Admission bilirubin (μmol/l)*	No. of pairs	No. of pairs Cr>177 μmol/l
I	<34	4	1
II	34–83	5	1
III	83–154	8	3

* Highest bilirubin during 2 weeks prior to randomization.

Table II: METHOD OF DIURETIC ADMINISTRATION

a. If low salt diet is unsuccessful, then:
    Aldactone 200 mg/day × 4 days
b. If 200 fails, then:
    Aldactone 400 mg/day × 4 days
c. If 400 fails, then:
    Aldactone 600 mg/day × 4 days
d. If 600 fails, then:
    add chlordiazide 50 mg/b.i.d.
    or
    frusemide 40–80 mg/t.i.d.

Surgical therapy

The preoperative preparation, operative technique and postoperative care have been described elsewhere (LeVeen et al., 1976; Wapnick et al., 1977). The operation performed under

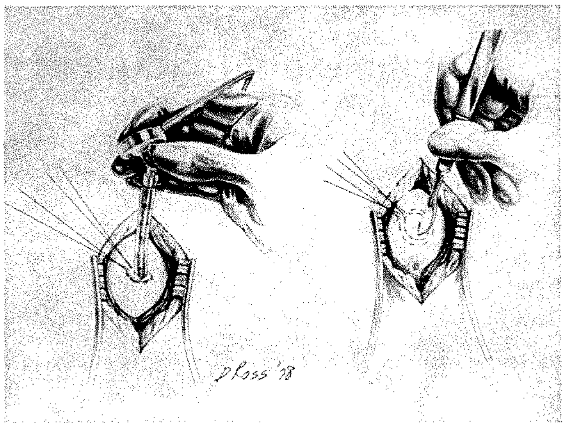

Fig. 1. LeVeen peritoneovenous shunt. A wide perforated portion is inserted into the peritoneal cavity: the valve is placed extraperitoneally and Silastic tubing tunnelled subcutaneously to the neck where it is inserted into the superior vena cava.

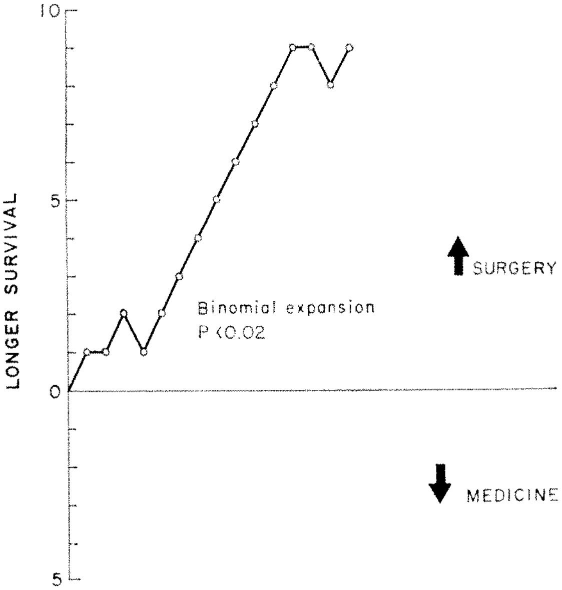

Fig. 2. Matched pair analysis of survival. Patients undergoing the shunt operation showed significant prolongation in survival compared with those treated by conventional methods (binomial expansion: $P<0{\cdot}02$).

local anaesthesia is relatively minor. Ascitic fluid is drained through a wide perforated Silastic tube into a one-way valve that is located extraperitoneally. A long, narrow silicone rubber tube attached to the valve is tunnelled subcutaneously to reach the neck where it is inserted into the superior vena cava (*Fig.* 1). To facilitate drainage through the valve after operation, the patient remains supine, an abdominal binder is worn and exercises designed to encourage maximal inspiratory effort are performed. Frusemide, 40–80 mg every 4–8 h, is administered intravenously initially and tapered after 3–4 days according to individual requirements. Dietary sodium intake after operation was between 1 and 2 g. Diuretics were prescribed if ascitic fluid reaccumulated at any stage in the postoperative period. Implanted valves have functioned satisfactorily for 3–4 years after insertion (LeVeen et al., 1976; Wapnick et al., 1978).

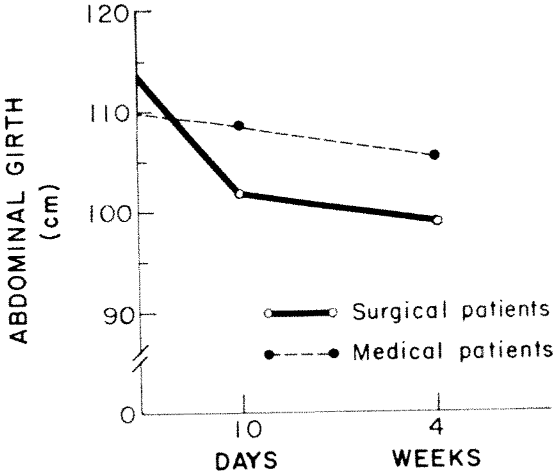

Fig. 3. Patients treated with peritoneovenous shunt showed significantly ($P<0{\cdot}001$) greater mean net loss in abdominal girth measurement.

PV, Peritoneovenous.

* Differences between values are considered significant if they exceed twice the standard error of difference.

† Two patients still alive are excluded as follow-up after shunt is less than 3 years. One patient in medical group was lost to follow-up 28 months after randomization.

The following measurements were performed before randomization: body weight, abdominal girth (at the umbilical level), 24-hour urine volume, complete blood count, serum electrolytes, creatinine, BUN, total protein, albumin and urine sodium and creatinine. Measurements were repeated 10 days after randomization. In both groups, data were collected at 4 weeks and on subsequent outpatient visits. The length of hospital stay and the development of complications were recorded.

Differences between medical and surgical patients were tested by the Wilcoxon test. Changes over the course of therapy for both groups were evaluated by the Friedman two-way analysis of variance. Results for survival were scored as positive for either treatment group (binomial expansion) if the patient survived at least 3 weeks longer than his matched partner.

Results

Of the 17 matched pairs, 12 surgical patients outlived their corresponding medical partners. Two medical patients lived longer than their surgical counterparts using the same criteria. Two pairs survived the same length of time. In one pair both individuals are still alive. It was thus possible to assess the difference in survival in 16 pairs.

Surgical therapy offered significant prolongation of survival (binomial expansion, $P<0{\cdot}02$, *Fig.* 2). Two

† Differences among the time periods.
The numbers in parentheses represent the number of subjects. Differences are due to patients having either left the hospital or died.

patients were shunted but at the time of completion of the study were not paired with a medically treated partner. Both patients responded favourably to the shunt and remained well and free of ascites at the conclusion of this study. Long term survival is shown in *Table III*. Median survival time for the pairs whose members have expired (9) was 57 days for those treated medically and 86 days for those shunted. The median hospital stay for pairs whose members left the hospital in good condition (9) was 32 days for those treated medically and 15 days for those shunted. Of the patients who were discharged, 5 in the medical group (median stay 26 days) and 7 of the surgical group (median stay 10 days), required readmission to the hospital.

The mean weight reduction was greater 10 days after treatment in the shunted patients (11·3 kg *v.* 3·7 kg) (*Table IV*). Both medical and surgical patients experienced significant weight reduction 4 weeks after randomization. A very significant reduction ($P < 0{\cdot}001$) in mean abdominal girth occurred in surgical patients over the first 10 days (12·7 cm) and at 4 weeks (14·9 cm) (*Table IV*). There was no significant change for medical patients at either time (1·1 cm and 4·2 cm respectively, *Table IV*). Maximal daily urine output was also significantly greater ($P < 0{\cdot}01$) in the surgical group during the first 10 days than in the medical group (medians 5815 ml *v.* 900 ml).

No significant changes occurred in the serum creatinine, albumin, sodium, calcium, phosphorus or creatinine clearance (*Tables IV* and *V*) during the treatment period in either the medical or the surgical patients. The medical patients, however, experienced a significant rise in BUN, whereas those shunted did not. Serum potassium was also elevated during medical therapy and lowered by operation (*Table V*).

The complications following medical and surgical therapy will be discussed elsewhere.

Discussion

In the United States alcohol abuse and its sequelae ranks as one of the five leading causes of death. Alcohol contributes significantly to absenteeism, decreased worker productivity and national morbidity statistics. The onset of ascites in the cirrhotic patient carries a grave prognosis (Garceau and Chalmers, 1963; Conn, 1973).

Conventional therapy of ascites aims at decreasing fluid accumulation by salt restriction and diuretics. Therapy for 'massive' ascites is usually ineffective.

Paracentesis and intermittent reinfusion of ascitic fluid rapidly decreases abdominal girth and results in weight reduction but has not significantly prolonged life (Clermont et al., 1967). Paracentesis, by precipitating a rapid fall in intravascular fluid volume, can be lethal (Papper, 1958). The continuous return of ascitic fluid to the venous system, when initiated at a time when the kidneys are refractory to diuretic therapy, is central to the success of the shunt (LeVeen et al., 1976; Wapnick et al., 1977). The surgical shunt corrects truly refractory ascites and the hepatorenal syndrome (Fuller, 1977; Wapnick et al., 1978). The present study shows that the insertion of the peritoneovenous shunt at an earlier stage offers significant prolongation of survival, more rapid correction of ascites and a shorter hospital stay. The therapy also protected against azotaemia, which was present 4 weeks after randomization in the non-surgical group.

The shunt operation should not be advocated indiscriminately for massive ascites (LeVeen et al., 1976; Wapnick et al., 1978). The incidence of postoperative complications and death is markedly increased in cirrhotics with jaundice (bilirubin greater than 153·9 μmol/l) or encephalopathy (Wapnick et al., 1978). Surgery should be considered if improvement in hepatic functions occurs but ascites persists or the hepatorenal syndrome supervenes. Removal of ascitic fluid prior to completion of the shunt procedure is indicated in the poor risk patient (Wapnick et al., 1978). There are several theoretical advantages to this approach. Fluid removal precludes the entry into the circulation of large amounts of ascitic fluid containing endotoxin (Tarao et al., 1977), thromboplastin-like materials (Lerner, 1971) and other as yet undetermined factors which may compromise the outcome. Tarao et al. (1977) in Japan noted that 17 of 23 (79·3 per cent) cirrhotic patients had endotoxin in the ascitic fluid. Recirculation of ascitic fluid by the peritoneovenous shunt did increase systemic endotoxin levels in 8 patients we have studied without any apparent adverse effects (unpublished data). Discarding of nearly all ascitic fluid at the time of surgery may also increase the safety margin of the shunt operation in preventing pulmonary oedema and cardiac failure as the intravascular compartment now receives ascitic fluid at a much slower rate. In the present study ascitic fluid was not discarded at the time of surgery. Further studies are indicated to predict preoperatively which components of ascitic fluid are likely to lead to complications. The possible role of haemodialysis combined with continuous fluid reinfusion requires further evaluation in patients in poor risk categories.

Patients with peritoneal sepsis (Conn, 1964) have a grave prognosis, and shunting of infected peritoneal fluid could lead to severe fulminating septicaemia. The shunt procedure is also contraindicated in patients with severe coagulation defects and those with recent variceal bleeding who have not had a decompressive procedure performed.

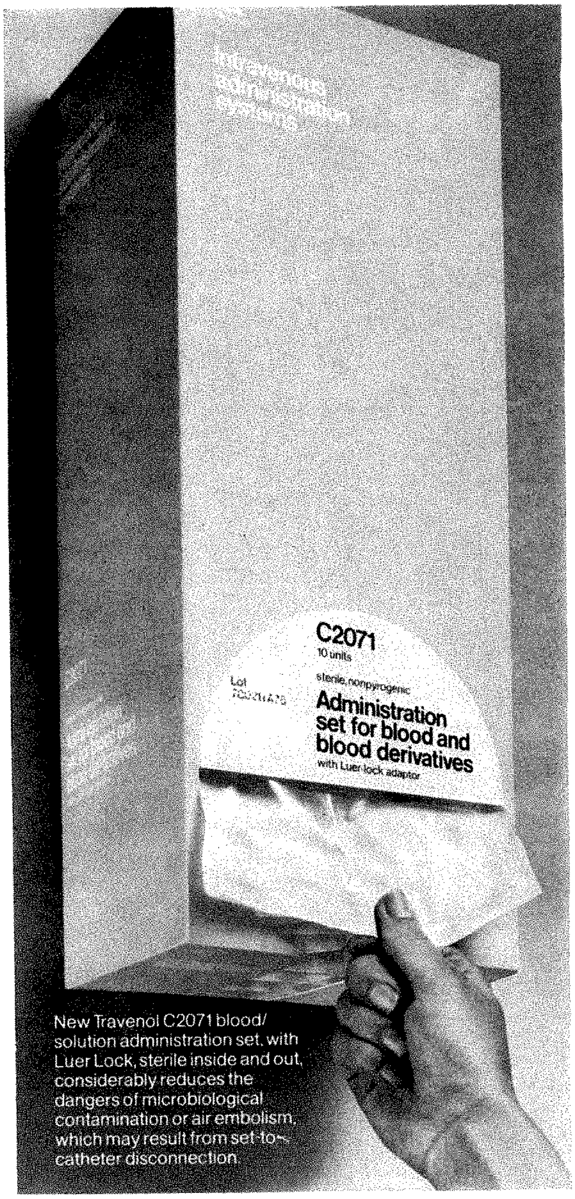
Travenol Sets the Standards



Intravenous administration systems
C2071
10 units
Lot
sterile, nonpyrogenic
Administration set for blood and blood derivatives
with Luer-lock adaptor

New Travenol C2071 blood/solution administration set, with Luer Lock, sterile inside and out, considerably reduces the dangers of microbiological contamination or air embolism, which may result from set-to-catheter disconnection.

Travenol intravenous administration sets exemplify three distinct standards of excellence.

A standard for design. Each set is designed to meet a known clinical need, and exhaustively tested to ensure that it does so.

A standard for manufacture. Rigorous quality control monitors every stage of production, from selection of raw materials to final sterilization, packaging and storage.

A standard for choice. The microbiological dangers of intravenous therapy can be reduced by choosing the right set for each procedure and so avoiding unnecessary connections.

For full details of the complete range of Travenol intravenous administration sets, please contact Marketing Services Department.

Travenol choice makes intravenous therapy safer

Preservation of the injured spleen*

MICHEL S. SLIM, NAJWA E. NAJJAR AND HENRY G. MISHALANY†

SUMMARY

Experience with suture repair of splenic lacerations in 14 children and 8 adults is reported. The youngest patient was 3 days old and the oldest 60 years. Adequate healing was confirmed by postoperative splenic scans with or without arteriography. The 2 deaths in this series were not related to the splenic repair and were due to associated major injuries. The course of illness in the remaining 20 survivors did not reveal a failure of this technique or a complication related to the use of this conservative approach. It is expected that salvage of the traumatized spleen will eliminate the risk of fulminant postoperative infections that may be fatal.

THE classic treatment recommended for a splenic injury is splenectomy. This may be followed by an overwhelming infection that can be fatal, especially in young children, and this can occur several years after operation (Ellis and Smith, 1966; Erickson and Burgert, 1968; Isa et al., 1974; Balfanz et al., 1978). This increased susceptibility to infection has been attributed to a decrease of IgM after splenectomy (Eraklis et al., 1967; Najjar et al., 1968; Walker, 1976) and to a disappearance of tuftsin, the phagocytosis-promoting peptide (Ellis and Smith, 1966; Najjar et al., 1968; Najjar and Nishika, 1970).

In view of the frequency of these serious postoperative septic complications, preservation of the traumatized spleen becomes imperative when this is technically possible. The present report is concerned with the conservative operative approach to splenic injuries in 22 patients admitted to the American University of Beirut Hospital during the period between 1 January 1973 and 31 December 1977.

Patients and methods

During the 5-year period studied 84 patients with splenic injuries were operated on, of whom 62 (73·8 per cent) required total extirpation of the spleen. Of the remainder, one patient underwent a partial splenectomy and 21 had suture repair of the splenic laceration. These cases form the subject of this report.

Fourteen patients were children, their ages ranging between 3 days and 15 years, and 8 were adults, the oldest being 60 years of age. In 12 patients the splenic injury was due to blunt trauma, in 9 patients it was inflicted by bullets or shrapnels and in 1 case, a 3-day-old infant, the cause of the laceration could not be ascertained.

Nineteen patients (86 per cent) had associated injuries to other organs or structures. In the case of blunt trauma, head injuries predominated, but other injuries to the chest, kidneys and extremities were also encountered. In the case of penetrating injuries, the associated lesions involved mainly the intra-abdominal organs and, less frequently, the lungs, head, peripheral vessels and bones.

The type of splenic injury varied from a single superficial laceration in 10 patients, to multiple lacerations of different depths in 7 patients and to deep lacerations with almost complete separation of the splenic segments in 5 patients. The surgical repair of splenic lacerations was accomplished by sutures of chromic catgut threaded on liver needles. An omental patch was included in the suture line in 5 cases and Gelfoam was applied over the site of repair in another 2 cases. The average duration of the procedure was 2 h when the injury was isolated to the spleen. Drains were left intraperitoneally at the end of operation in 6 of the 22 patients. Drains were used when the injury involved the gastrointestinal tract or liver or when there was associated retroperitoneal bleeding. Drains were also used in the case of partial splenectomy. The drains were removed either 48 h or 7 days after operation. Broad spectrum antibiotics were administered systemically in the majority of patients. The period of hospitalization ranged from 6 to 15 days with an average of 11 days for children and 23 days for adults, the longer period being observed in patients with multiple injuries.

Results

Two deaths occurred, both in the adult age group. One patient, who was 22 years old, had injuries involving the spleen, lungs, bowel and iliac vessels. He developed peritonitis, renal failure and bleeding from the iliac region which led to his death 5 days after operation. The other patient, who was 31 years old, had injuries involving the spleen, liver, lung, gastrointestinal tract and extremities. He succumbed on the eighth postoperative day. In the remaining 20 survivors, complications were noted in 4 patients. They consisted of wound haematoma and atelectasis with pneumonia in 2 children and superficial wound infection due to *Escherichia coli* in 2 adults.

A clinical follow-up ranging from 1 month to 2 years was obtained on 11 of the 20 survivors. The remainder could not be traced and the course of their illness after discharge remains unknown.

In 9 patients adequacy of the healing was checked by a splenic scan, using technetium sulphur colloid. The scan was done from 9 days to 2 years after operation. On 7 scans healing was reported to be normal. On 2 the scar in the spleen was visible radiologically as a linear defect. In one child whose spleen was fractured into two pieces a splenic arteriogram and scan were performed on the ninth day and repeated 2 months after operation, confirming complete healing of the laceration. In cases where splenic scans were done sequentially to determine the progress of healing, the uptake of the isotope, which was decreased initially, became normal in later studies.

Discussion

Until recently, splenectomy has been recommended as the best treatment for splenic lacerations. Our recent experience suggests that this is necessary in less than one-half of the cases; the remainder can be managed successfully by a primary repair of the laceration *in situ*. The safety of the latter technique is confirmed by the long term observation of these patients. Preservation of the spleen deserves serious consideration in all age groups especially children, in order to avoid the development of overwhelming infections secondary to asplenia (Editorial, 1976; Ravry et al., 1972).

* Presented at the 25th Annual Congress of the British Association of Paediatric Surgeons, Edinburgh, 26–30 June 1978.

† Departments of Pediatrics and Surgery, School of Medicine, American University of Beirut, Beirut, Lebanon.

The conservative surgical approach to splenic injuries dates back to 1945 (Foster and Prey, 1940; Mazel, 1945). Work on preservation of the traumatized spleen in the experimental animal dates back to 1962 (Christo, 1962; Morgenstern et al., 1966; Morgenstern, 1974; Fitzer, 1976). No successful results were achieved until Bodon and Verzosa (1967) reported the use of Gelfoam for iatrogenic splenic injuries. Douglas and Simpson (1971) reported their experience with the conservative non-operative management of splenic trauma and contested that bleeding from a splenic laceration had usually stopped by the time of laparotomy. Microcrystalline collagen haemostat (Avitene) was reported useful in the control of bleeding from the spleen (Hait, 1970; Morgenstern, 1974). The application of peritoneal patches and butyl-2-cyanoacrylate monomer was also found by Orda et al. (1974) to be beneficial for the repair of splenic lacerations. Encouraged by these results, one of us reported his experience on surgical repair of the injured spleen in 8 children (Mishalany, 1974).

The use of the Hickman catheter in the management of patients with leukaemia and other malignancies

MEIRION THOMAS

SUMMARY

The use of the Hickman right atrial catheter in 25 patients with leukaemia and other malignancies is reported, and it is concluded that with careful selection of patients, the benefits of this semi-permanent catheter outweigh the risks of infection. The catheter may be useful in the intensive care of children or adults with non-malignant conditions.

PROLONGED failure of bone-marrow and the gastrointestinal tract are frequent complications of cancer treatment by methods such as high-dose chemotherapy or total body irradiation with allograft bone-marrow reconstitution. Efficient long term access to the central circulation for haematological, antibiotic and nutritional support is essential in the management of such patients.

Patients and methods

The Hickman right atrial catheter (*Fig.* 1) consists of a 90-cm length of Silastic tubing with a connector at one end which can either be attached to an intravenous infusion set or sealed with a catheter cap after anticoagulating the catheter with 2 ml of 500 units/ml heparin. A Dacron cuff is glued a third of the way along the catheter and this becomes invaded by healing tissues to provide fixation and to protect against infection tracking along the outside of the catheter.

The catheter is most conveniently inserted into the cephalic vein at the deltopectoral groove under local or general anaesthesia (*Fig.* 2). After ensuring that the isolated cephalic vein is patent and wide enough to take the catheter a long subcutaneous tunnel is constructed with a straight artery forceps to come out low on the anterior chest wall. The catheter tip is grasped in the jaws of the artery forceps and the catheter is drawn through the subcutaneous tunnel until the Dacron cuff lies midway between the exit site and the vein. The length of Silastic tubing required to reach the midpoint of the right atrium is estimated and the catheter trimmed appropriately before threading into the cephalic vein. The position of the catheter must be checked by X-ray or fluoroscopy, and revised

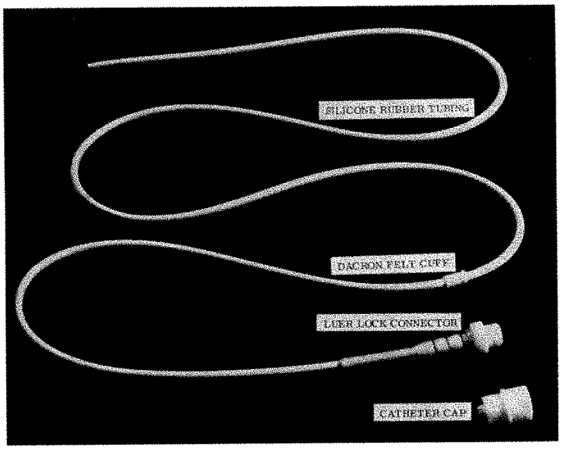

Fig. 1. The Hickman right atrial catheter.

unless satisfactory. The catheter should be fixed to the skin at the exit site to prevent accidental removal until the Dacron cuff is invaded by healing tissues. Daily catheter care consists of cleansing of the exit site and application of a sterile dressing.

In children below the age of 5 years the cephalic vein is too narrow to accept the diameter of this catheter and an alternative method of insertion into the internal jugular vein is used, similar to the method described for insertion of the Broviac catheter (Heinbach and Ivey, 1976). A small incision is made behind the posterior border of the sternocleidomastoid muscle immediately above the clavicle. The muscle is retracted anteriorly and the internal jugular vein is isolated between two stay sutures. A fine purse string suture is placed in the lateral wall of this vein and an appropriate length of Silastic tubing is threaded through a tiny venotomy. It is important that the subcutaneous tunnel enters the neck wound at its lateral extremity to allow as wide a sweep as possible before the catheter turns back on itself to enter the vein (*Fig.* 3). 'Hairpin' angulation in the neck will result in early catheter failure. The platysma is approximated with catgut sutures and the skin with fine nylon.

Results

Most of the patients in this series were children and young adults in remission from acute lymphoblastic or myeloblastic leukaemia who were being treated by total body irradiation and allograft bone-marrow reconstitution. Two patients with leukaemia were not in remission at the time of placement of the catheter. The series also includes 5 children with neuroblastoma being treated with high dose Melphalan, and 4 patients with complications of gastrointestinal malignancy.

Infective complications occurred twice in this series necessitating removal of the catheter. Both patients had acute myeloblastic leukaemia and neither was in remission. Both infections were associated with silk skin sutures used in one case to close the neck wound and in the other case to secure the catheter at the exit site. All the other catheters functioned normally without complication for 28–70 days (median time of 42 days) until they were removed at the end of treatment. Many patients were severely thrombocytopenic at the time of placement of the catheter and no complication from haemorrhage was seen, although platelet transfusion was given as a precaution immediately before surgery.

The catheter is removed by making a small incision over the Dacron cuff under local anaesthesia and dissection of the cuff from the surrounding tissues. Histological sections of the Dacron cuff after removal show dense infiltration of the interstices by fibrous tissue and abundant foreign body giant cells.

Discussion

The Hickman right atrial catheter has proved to be of great benefit in the management of patients requiring prolonged haematological and nutritional support, especially those undergoing bone-marrow transplantation. In this group of patients previous treatments have invariably thrombosed all peripheral veins and it is essential to be able to guarantee efficient access to the central circulation for the duration of parenteral support. Blood and blood product transfusions particularly predispose to clotting of cannulas, but at no time did a Hickman catheter thrombose despite frequent transfusions of whole blood, platelet and granulocyte packs, whole plasma, fresh frozen plasma, plasma protein fraction and salt-poor albumin. The catheter was used for total parenteral nutrition and to correct the frequent fluid and electrolyte imbalances associated with the treatment and complications of bone-marrow transplantation. For example, the intense diarrhoea of graft versus host disease and the distal renal tubular dysfunction associated with acute myeloid leukaemia, gentamicin and carbenicillin therapy required prompt correction. All antibiotics, cytotoxic agents and other necessary parenteral chemotherapy were administered via the catheter. Finally, the catheter was used for blood sampling and this was especially appreciated by the children, who were spared daily venopuncture. The facility to heparinize and seal the catheter is useful towards the end of treatment to allow children to play free of the encumbrances of giving-set and drip-stand and to allow both children and adults to leave hospital occasionally as condition permits.

In such a severely immune-suppressed group of patients, the benefits of this catheter must be weighed against the danger of infection. Patients with good peripheral veins who are likely to require haematological and nutritional support for a short time are better managed by other methods of cannulation. Patients with acute leukaemia who are not in remission probably have the greatest risk of infection, and the use of this semi-permanent catheter should be avoided until all other methods have been exhausted.

In this paper the use of the Hickman catheter is described only in the management of cancer, but its versatility allows it to be applied to other situations. It may be useful in paediatric non-malignant intensive care or in the management of patients with temporary gastrointestinal failure from such conditions as regional enteritis. The similar Broviac catheter has been described frequently as a permanent home hyperalimentation catheter (Broviac and Scribner, 1974; Broviac et al., 1975; Riella and Scribner, 1976), but the wider Hickman catheter is preferable in patients who require frequent blood and blood product transfusions.

Acknowledgements

Thanks are due to Dr T. J. McElwain, Dr R. Powles and Dr H. Clink for allowing me to report cases admitted under their care. I am grateful to Dr R. O. Hickman, Department of Medicine, University of Washington, Seattle, Washington 98195, USA, for personal communications regarding the placement of this catheter. Thanks also go to Miss Lynn Baxter who typed the manuscript.

The Hickman catheter can be obtained from Evergreen Medical Products Inc., PO Box 296, Medina, Washington 98039, USA.

A suction cannulator for rapid peroperative cholangiography

A. M. HAY*

THE new instrument described here facilitates peroperative cholangiography and has particular advantages in the situation where cholecystectomy has been performed previously, where cystic duct identification and isolation are difficult, or where there is an awkward arrangement to the spiral valve of Heister.

Fig. 1 shows the suction cannulator in diagrammatic form. The principles underlying its design are as follows. The footpiece (A) is applied to the common bile duct and is held securely in place by suction (a standard operating theatre sucker is satisfactory) through channel (B). The device, held in this way, is not displaced by removal of packs or retractors. Gentle traction on the instrument separates the walls of the bile duct and thus produces a favourable configuration for insertion of a 23G × 25 mm needle through the needle guide (C) into the lumen of the bile duct. The length of the needle guide (C) is such that the needle cannot protrude from the footpiece by more than 4 mm. This distance has been found suitable for use in most sizes of duct, whether thin- or thick-walled. A small crimp in the needle guide grips the needle firmly. The expanded end of the needle guide ensures that the puncture site in the bile duct is not directly exposed to the suction force in the footpiece, and thus prevents excessive extravasation of bile or contrast medium.

Operation of the device is simple. The position and direction of the common bile duct are identified. It is best, though not essential, to clean off the covering peritoneum and fat so that the surgeon may be confident as to the alignment of the duct, and that no important structure, such as the hepatic artery, overlies the duct at the point where the device is to be applied. With suction connected and the needle, attached by suitably primed small-bore tubing to a syringe, lying loosely in the needle guide, the instrument is introduced into the wound. The suction channel serves as a convenient handle, the angle it makes with the footpiece facilitating placement high up under the liver if necessary. The footpiece is aligned with and applied to the duct. Once a suction seal has been obtained, the duct can be tented gently upwards and the cannulating needle pushed home in the needle guide. Aspiration of bile confirms a successful cannulation. After a little practice, it is possible to perform the whole procedure in just a few seconds.

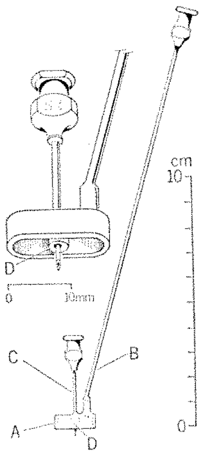

Fig. 1. Diagram of the suction cannulator: A, footpiece; B, suction channel and handle; C, needle guide; D, expanded end of needle guide.

The device has so far been used in 20 operations, satisfactory cholangiograms being obtained on 18 occasions. The device is not suitable for use, however, where there is a very narrow common bile duct; this was the cause of our 2 failures. Occasionally the bile duct may be a little distorted at the point of application of the device. This has not led to any errors of interpretation and may, in any case, be circumvented by the simple expedient of releasing suction and removing the device once the full volume of contrast medium intended for injection has been introduced into the biliary tree; the final X-ray film is then sure to be free of artefact.

The application of strong suction forces to the bile duct for periods of up to 10 min has not been associated with any detectable injury to that structure. Use of the fine needle has apparently prevented the development of annoying biliary leaks without providing any significant obstruction to the injection of contrast medium.

The new device, constructed in metal and plastic, is available in presterilized disposable form from Portex Ltd, Hythe, Kent.

Acknowledgements

The author wishes to express his gratitude to Messrs Derek Chappell and John Fearn of the Royal Postgraduate Medical School and to Mr David Cross of Portex Ltd for their expert technical assistance in the development of the suction cannulator. Mr Doig Simmonds of the Department of Medical Illustration, Royal Postgraduate Medical School, kindly provided the diagram.

Paper accepted 28 February 1979.

Book reviews

Modern Cardiac Surgery

D. B. Longmore. 240×160 mm. Pp. 393. Illustrated. 1978. Lancaster: MTP. £14·95.

THE course on cardiac surgery organized each year by the British Postgraduate Medical Federation has become an academic landmark on the calendar of all those who have a special interest in this subject.

This book is an up-to-date account of the growing edge of cardiac surgery as seen in April 1977 and covers many topics that are now becoming more clearly defined and better understood. Of particular interest today are the chapters on transplantation of the heart, mitral valve conservation, the preparation, preservation and use of tissue valves and the management of their complications. Frequent reference is made to echocardiography and one chapter is devoted to this subject. The section on elective cardiac arrest, myocardial preservation and left ventricular function is a useful appraisal of a subject which is still fraught with controversy and individual opinion.

The major emphasis is on the surgery of the more complicated forms of congenital heart disease. Here technical surgical procedures are described in detail with many excellent illustrations. Complications, snags and even failures are discussed in a way that is not possible in the journals or a standard textbook.

This book will be a valuable record for those who attended the course in 1977 and a useful reference for others. It is not a book that one would wish to read from cover to cover but each chapter reads easily, indicating considerable revision of the spoken word. If this book is kept alongside the published proceedings of earlier and subsequent conferences, a useful shelf on fashions and trends in cardiac surgery will soon be established.

J. W. JACKSON

Sémiologie Chirurgicale

Professor L. Leger et al. Fourth edition. 280×215 mm. Pp. 503 +xiii. Illustrated. 1978. Paris: Masson. No price given.

IT is a pleasure to review the fourth edition of *Sémiologie Chirurgicale* by Professor Lucien Leger and his colleagues. It has been translated into German, Spanish, Italian, Iranian, Japanese and Turkish, which speaks highly of its format as a primer in surgical practice for the undergraduate and postgraduate.

The line drawings are full of Gallic wit, each making its point dramatically, often very amusingly. The X-rays are good and to the point. It is profusely illustrated in black and white. It is a shorter edition of Bailey and Love and is in a similar way didactic but orthodox. It is essential reading for anyone wishing to gain a rapid knowledge of French medical terminology. It can be highly recommended.

J.-C. GAZET

Amputation and Prostheses

M. Vitali, K. P. Robinson, R. G. Andrews and E. E. Harris. 245×185 mm. Pp. 241+ix, with 167 illustrations. 1978. London: Baillière Tindall. £10·50.

THIS work is directed primarily at the young surgeon in training. It contains enough technical information to guide him through all but the most obscure levels of amputation. The book covers in considerable detail the important matters of preoperative assessment and selection of level, with due regard to the prosthetic implications. Postoperative care and rehabilitation are dealt with adequately and there is a unique survey of modern British prosthetic practice.

This is a clearly written and polished work encompassing several disciplines. It is likely to be read with interest by all those involved in the care of amputees, whether they be new to the field or old hands.

J. C. ANGEL

Surgical Conditions in Paediatrics

H. Homewood Nixon. 216×138 mm. Pp. 448. Illustrated. 1978. Sevenoaks: Butterworths. £23·00.

THE author, in his preface, indicates that this book was written mainly for medical paediatricians. Nevertheless, it is an invaluable book for general surgeons, who still, as he points out, carry out most of the ordinary surgery of children. The book deals in detail with diagnosis, differential diagnosis and management, just those areas where the general surgeon feels himself at a disadvantage when cooperating with his medical paediatric colleagues. The place of surgery in the overall management, the choice of operation, its timing and problems of pre- and postoperative care are most fully discussed. There is no step-by-step description of operations but there are many helpful and illuminating details of operative technique—sufficient to make a surgeon wish that this aspect had been developed more fully. This is one of the new medical books that could be wished longer. Nevertheless it is churlish to complain where so much has been provided. The book covers the whole field of paediatric surgery with the exception of orthopaedics. It is lucidly written, purposefully illustrated and garnished with well-chosen references, benefiting greatly from being written by one man with the authority of long personal experience and eminence in this specialty. Despite the somewhat startling price, the book is to be recommended for any surgeon dealing with children.

A. CAMERON

Transurethral Resection

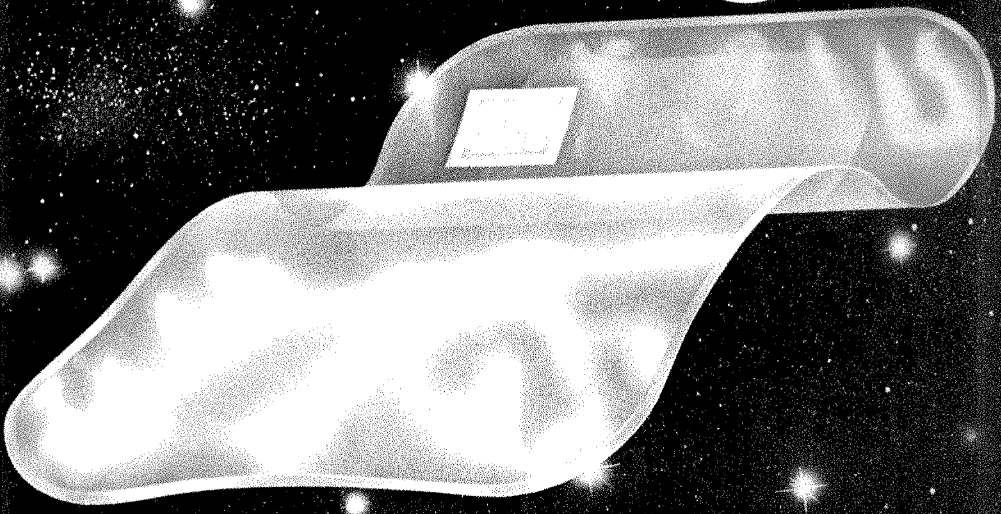
Professor J. Blandy. Second edition. 250×190 mm. Pp. 184+vii. Illustrated. 1978. Tunbridge Wells: Pitman Medical. £14·00.

IT is always a pleasure to read the works of Professor John Blandy, and this new edition of *Transurethral Resection* is no exception. Throughout, the text is easy to read and the illustrations by the author's hand are succinct and clear. Opening with a brief historical review, the author clearly covers the current instruments and equipment, and explains, in simple language, their workings. The indications for transurethral resection are carefully explained. There now follows a superb description of basic resection skills, and then an exciting description of how the author himself resects a benign prostate. He describes shamelessly all the pitfalls and how to get out of them. An acknowledgement of, and the technique employed in, bladder-neck incision is somewhat thin. As this book is on transurethral resection, the techniques for resecting bladder tumours are described. A brief description of the author's preferences for managing bladder tumours is outlined. The management of the larger solid tumours, T3 and 4, is unfortunately lumped together, and it would appear that the same treatment applies to both. Likewise, the impression is given that in the combined management of T3 bladder tumours by radiotherapy and surgery, it is preferable to employ 6000 rad, as opposed to 4000 rad, in the preoperative period; this is, of course, not the modern teaching. The author, quite correctly, covers the coexistence of bladder stones and the management of these in combination with bladder neck obstruction. The book finishes with a description of the all-important postoperative care and complications, early and late. It is surprising that urea levels are measured in milligrams per cent, and also to learn that the Kidd–Riches big ball diathermy cystoscope is now obsolete!

This is a masterful description of Professor Blandy's techniques, which have aided and abetted many past and present RSOs both at St Peter's and the London Hospital. It is clearly complementary to other books on the subject, and will be avidly read, not only by trainee resectionists but by all who practise this technique.

P. R. RIDDLE

Hollister conquers gas



At last-a highly effective flatus filter from Hollister

No leaks, no odour — Hollister have made sure that this new deodorising flatus filter is really effective and trouble-free.

Every colostomy patient knows the discomfort and embarrassment that occurs when a stoma bag swells up with flatus. Now Hollister have developed a flatus filter system that solves this problem successfully. Laboratory trials have proved its reliability.

Gas is released automatically through the unique Hollister* deodorising filter — packed with thousands of tiny odour-trapping granules of activated charcoal.

No leaky filter, no odour, no more discomfort or embarrassment. It really works. Hollister have conquered gas!

You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. —The ubiquitous staph. needs an ubiquitous antibiotic — penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole fucidin

FUCIDIN (sodium fusidate B.P.)
Dosage:
Adults: 500 mg (2 capsules) 3 times daily with food.
Children: 20-40 mg/kg body weight daily in 3 divided doses with food.
The standard dose may be doubled for initial therapy in severe infections.
Adverse reactions and precautions:
After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.
Product Licence No: 0043/5019.
Each capsule contains 250 mg sodium fusidate B.P.

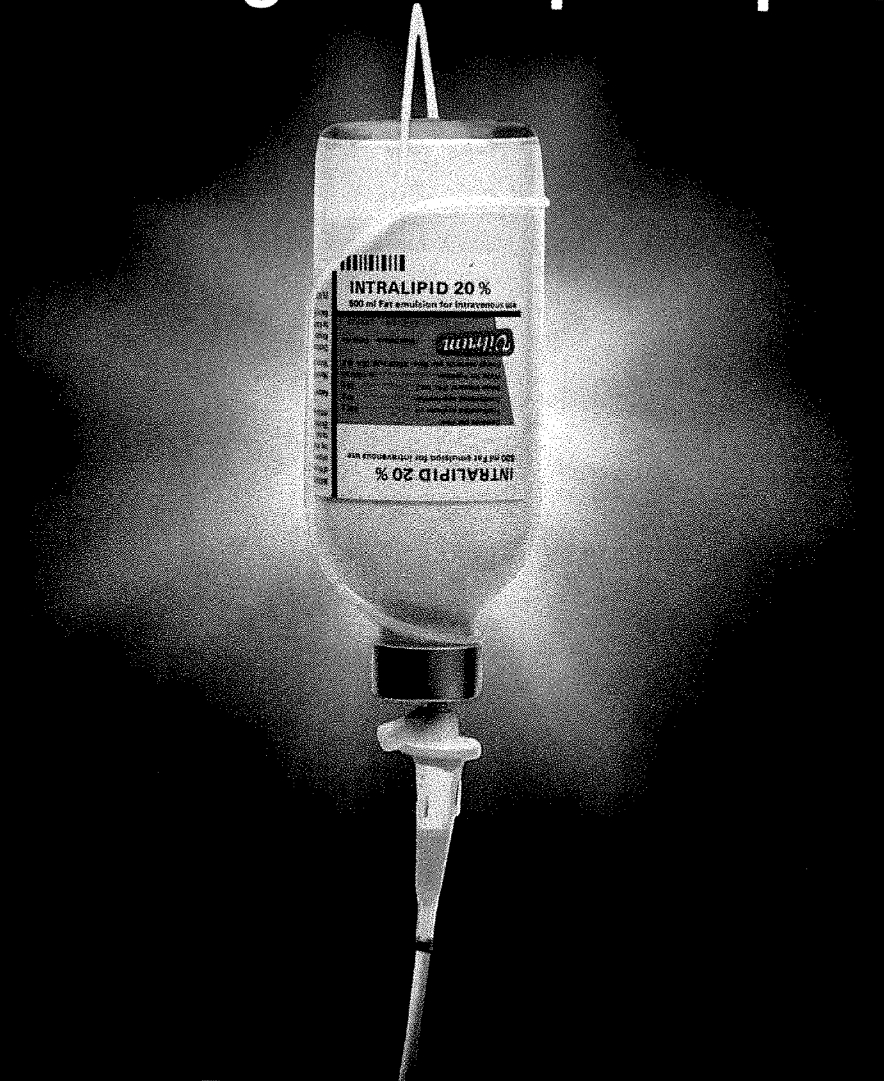
How to strengthen the post-op life line



INTRALIPID 20 %
500 ml Fat emulsion for intravenous use
Vitrum
INTRALIPID 20 %
500 ml Fat emulsion for intravenous use

Intralipid®

soya bean oil emulsion 10% and 20%

the most concentrated source of energy for central and peripheral infusions from the world leaders in complete intravenous nutrition

PRESCRIBING INFORMATION

INTRALIPID 10% INTRALIPID 20%

Presentation A milky white oil-in-water emulsion.

	Intralipid 10%	Intralipid 20%
Fractionated soya bean oil	50 g	100 g
Fractionated egg lecithin	6 g	6 g
Glycerol (anhydrous) (Ph. Int.)	12.5 g	12.5 g
Water for injections to 500 ml		

pH c. 7. The solution is sterile and pyrogen free.

Uses When feeding patients intravenously, the possibility of providing a sufficient amount of energy in the form of carbohydrate is limited by such considerations as hypertonicity, hypervolaemia and the tendency to thrombophlebitis. The development of fat emulsions has overcome these problems. Fat has a high energy value (9.3 calories per gram) and by the use of fat emulsion it is possible to provide a high calorie intake in a relatively small fluid volume. Fat emulsions also have a protein-sparing effect when given in conjunction with amino acid solutions to correct negative nitrogen balance. The intravenous fat emulsion Intralipid is metabolised in the same way and at the same rate as normal chylomicrons. One litre of Intralipid 10% provides 1,100 calories and 1 litre of Intralipid 20% provides 2,000 calories.

Indications Intralipid fat emulsions are indicated in conditions of severe protein depletion requiring also a high energy intake to compensate for excessive loss of calories following trauma, infection, fever, burns, etc.

Dosage and administration Intralipid 10% 500–1,500 ml daily in conjunction with intravenous amino acids. For increased caloric requirements Intralipid 20% 500–1,500 ml daily in conjunction with amino acids. Intralipid 10% and 20% are administered by slow intravenous infusion. During the first 10 minutes the drip rate should be adjusted to 20 drops per minute and after half an hour this can be adjusted to a final rate of 60 drops per minute. 500 ml of either emulsion should be given in not less than three to five hours on the first day of infusion. On the first day of infusion it is advisable to administer 10 ml Intralipid 10% or 5 ml Intralipid 20% per kg body weight. Subsequently the dose is usually doubled, and when a larger intake is indicated it may be increased to 3 g fat per kg body weight.

Infant dosage Intralipid 10% or 20%, 15–20 ml per kg body weight in 24 hours.

Contra-indications, warnings, etc. Intralipid is contra-indicated in pathological hyperlipaemia and severe liver damage.

Precautions When daily intravenous fat administration for more than one week is indicated it must be ascertained, in order to prevent the development of cumulative lipaemia, that the patient is capable of eliminating the infused fat from the circulation, and this function can be tested in the following manner. In the morning following the first day's infusion, a citrated blood sample is drawn, preferably when the patient is still in a fasting state. The blood sample is centrifuged at 1,200–1,500 rpm. If the plasma is then strongly opalescent or milky further infusion should be postponed. In the great majority of cases, plasma is completely clear 12 hours after the conclusion of an infusion of 2 g fat per kg body weight (corresponding to 20 ml of Intralipid 10% or 10 ml of Intralipid 20% per kg body weight). This test should be repeated at weekly intervals.

Pharmaceutical precautions Store at a temperature between 4°C and 8°C and do not use after the date of expiry indicated. The contents of each bottle are for a single infusion and any residual emulsion should be discarded. No drugs should be added to Intralipid prior to or during infusion.

Legal category No legal restrictions on sale or supply.

Package quantities Intralipid 10%: 100 ml and 500 ml. Intralipid 20%: 100 ml and 500 ml.

Further information Nil.

Accordingly, the publishers and the editorial committee and their respective employees, officers and agents accept no liability whatsoever for the consequences of any such inaccurate or misleading data, opinion or statement.

Editorial Notices and Instructions to Authors

Original articles and any other editorial matter should be sent to the *Editor, British Journal of Surgery, John Wright & Sons Ltd, Broadmead House, 21 Panton Street, London SW1Y 4DR.* Acceptance is on the understanding that contributions are to this journal only and that articles and their illustrations become the property of the journal unless rights are reserved before publication.

Business communications should be sent to *John Wright & Sons Ltd, British Journal of Surgery, Bristol BS8 1EX.* Remittances are payable to the *British Journal of Surgery.*

Advertisements: All communications to *Hexagon Publishing Co. Ltd, 7a Chequer Street, St Albans, Herts AL1 3YJ* (telephone St Albans (0727) 60641: telex 21827).

Manuscripts

The *British Journal of Surgery* subscribes to the policy of uniform requirements for manuscripts described in *British Medical Journal* 1979; **1**: 532–5 and *Lancet* 1979; **1**: 428–31, which authors are advised to consult, and in the leaflet *Uniform Requirements for Manuscripts Submitted to Biomedical Journals*, which is available from the Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p). The recommendations below are those which contributors to this journal *must* observe.

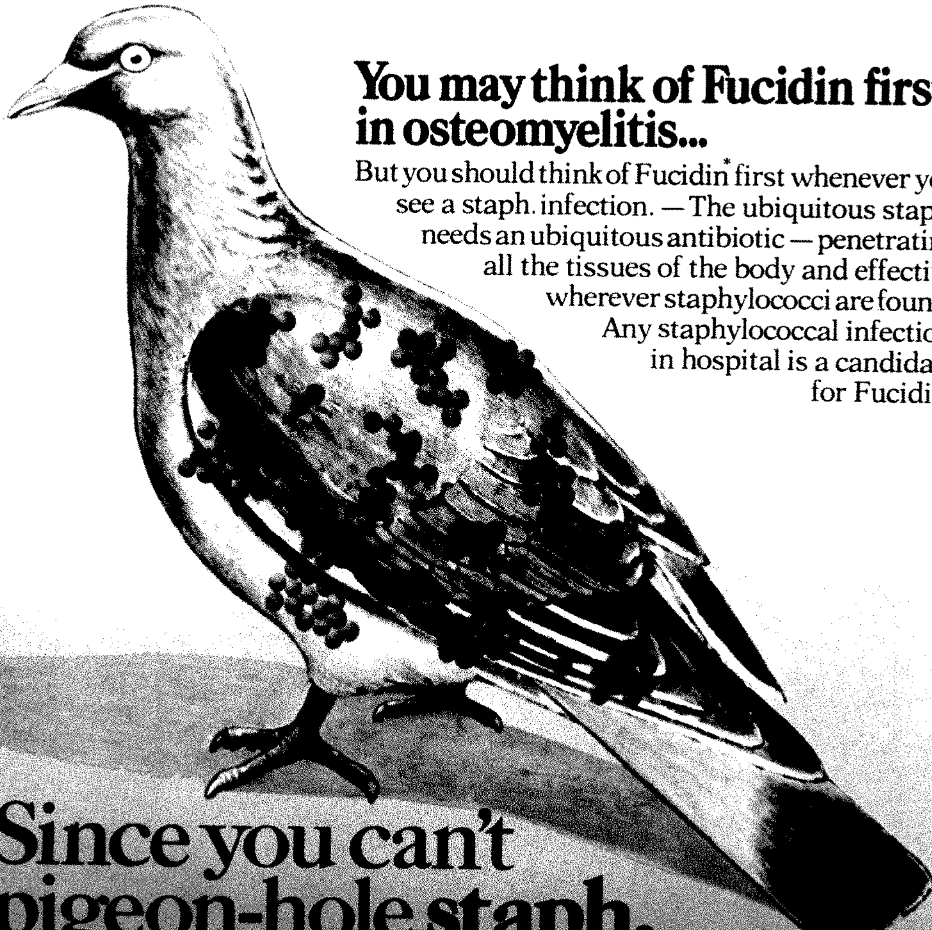
Submit three good quality plain paper photocopies of all written and tabular material and retain the original. The manuscript should be typed double spaced with 3-cm margins on ISO A4 (212 × 297 mm) paper or near equivalent and follow this sequence (beginning each section on a new page): title page (with authors, their highest academic degree, address of author who will deal with correspondence and sources of support; abstract and keywords (3–10 words or phrases using terms from *Index Medicus* whenever possible); text; acknowledgements; references; tables; and legends for illustrations. The abstract must be complete in itself, outlining the aim, results and conclusions of the paper. Tables should be typed each on a separate sheet and *must* have a Roman identifying number and a short descriptive heading. Submit all illustrations in triplicate and package securely. Photographs should be good quality, unmounted, glossy prints (not X-ray negatives or slides). Line drawings should be professionally drawn and photographed. A leaflet giving details of the preparation of artwork is available from the Editorial Office (enclose s.a.e.) and must be consulted. Colour prints should be accompanied by the original transparencies or negatives: a contribution towards the cost of colour reproduction is nearly always necessary. All illustrations should have a label pasted on the back indicating the name of the author(s), the figure number and the orientation, and, for photomicrographs, the original magnification. Do not write in pencil or ink on the back of photographs.

SI units and abbreviations

It is journal policy to use SI units except for measurement of blood pressure, where mmHg is preferred. Abbreviations for SI units and statistical terms are those in Baron D. N. (comp.): *Units, Symbols and Abbreviations: a Guide for Biological and Medical Editors and Authors*, 3rd ed. London, Royal Society of Medicine, 1977, and *Br. Med. J.* 1978: **1**: 1334–6. Other useful works are: Council of Biological Editors: *CBE Style Manual*, 3rd ed. Washington, American Institute of Biological Sciences, 1972; and O'Connor M. and Woodford P.: *Writing Scientific Papers in English, an ELSE–Ciba Foundation Guide for Authors.* London, Pitman, 1978.

References

In the text, references should be numbered consecutively in arabic numerals within parentheses (1, 2, 3 . . .). References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The reference list is typed in numerical order. All references cited should be listed according to the form of references adopted by *Index Medicus*. Where a journal is not listed by *Index Medicus*, give the full title. Up to six authors can be listed; if the number exceeds six quote the first three followed by et al. The sequence for a standard journal article is: author(s), title, journal, year, volume, first and last page numbers. The sequence for a book is: author(s), editor(s) or compiler(s); title; edition number; place of publication; publisher's name; year of publication; first and last pages of reference (if relevant).



You may think of Fucidin first in osteomyelitis...

But you should think of Fucidin* first whenever you see a staph. infection. —The ubiquitous staph. needs an ubiquitous antibiotic—penetrating all the tissues of the body and effective wherever staphylococci are found. Any staphylococcal infection in hospital is a candidate for Fucidin.

Since you can't pigeon-hole staph, you can't pigeon-hole fucidin

FUCIDIN (sodium fusidate B.P.)

Dosage:

Adults: 500 mg (2 capsules) 3 times daily with food.

Children: 20-40 mg/kg body weight daily in 3 divided doses with food.

The standard dose may be doubled for initial therapy in severe infections.

Adverse reactions and precautions:

After 14 years of widespread clinical use no pattern of toxicity to Fucidin has emerged. Gastro-intestinal upset occurs in some patients taking oral Fucidin. This can be minimised by taking the capsules with food or using Fucidin Enteric Coated Tablets. In some patients treated with either oral or I.V. Fucidin, jaundice has been reported. It has been extremely difficult to decide whether Fucidin, other drugs or the infection itself was responsible. Fucidin is excreted mainly in the bile and liver function tests should be carried out in patients with liver dysfunction, when used for prolonged periods or when administered in conjunction with other drugs which may compete for the same excretory pathway.

Product Licence No: 0043/5019.

Each capsule contains 250 mg sodium fusidate B.P.

Leo Laboratories Limited,
Hayes Gate House, Hayes, Middx.

QUESTIONS AND ANSWERS IN GENERAL SURGERY

H. P. HENDERSON, FRCS, *Senior Registrar, Plastic and Jaw Surgery, Fulwood Hospital, Sheffield;* and M. J. KELLY, MChir, FRCS, MRCP, *Senior Registrar in General Surgery, Bristol Royal Infirmary*

With a Foreword by The Right Hon. the Lord Smith of Marlow, KBE, MS, FRCS

This book contains questions and answers suitable for candidates revising for the Final FRCS Examination in General Surgery. The whole field for the examination is covered including subspecialties. The questions are laid out in random fashion to lessen the tedium of learning section by section and the answers have been placed adjacent to the questions. An index has been provided to enable readers to work through particular sections of their revision if they so wish

Anaerobic Bacteria

"...the major cause of sepsis after surgery of
the gastrointestinal tract
or female genital
tract".

Br.Med.J. **i**, 318, 1976

NOW
FLAGYL
METRONIDAZOLE
INJECTION
FOR INTRAVENOUS INFUSION

proves decisive in anaerobic infections

Only with recent improvements in bacterial culturing techniques has the pathogenic role of anaerobes in post-surgical infections been fully recognized.[1-3] Now 'Flagyl' Injection offers you a decisive means of treating these infections – which are often life-threatening and often resistant to established antimicrobials. The response to 'Flagyl' Injection is rapid and dependable,[2] as it is consistently bactericidal to pathogenic anaerobes at tissue concentrations easily achieved in treatment. Bacterial resistance is not a problem,[2-4] and 'Flagyl' is highly acceptable – as eighteen years of use in other indications has established.

osage: Treatment: adults and children over 12 years: 100 ml by intravenous
fusion eight-hourly, administered 5 ml per minute. Oral medication with 400 mg
ree times daily should be substituted as soon as this becomes feasible. Treatment
r seven days should be satisfactory in most cases. Children under 12 years: as
r adults but the single intravenous dose is based on 1.5 ml (7.5 mg
etronidazole) per kg bodyweight and the oral dose on 7.5 mg per kg bodyweight.
revention: adults and children over 12 years: 100 ml by intravenous infusion
mediately before, during or after operation, followed by the same dose eight-
ourly until oral medication (200 to 400 mg three times daily) can be given to
omplete a seven-day course. Children under 12 years: as for adults but the single
travenous dose is based on 1.5 ml (7.5 mg metronidazole) per kg bodyweight
nd the oral dose on 3.7 to 7.5 mg per kg bodyweight. Precautions: pregnancy;
ctation; clinical and biological surveillance if recommended duration of treatment
xceeded; dosage may be halved for patients with renal failure; avoid alcohol; if
lagyl' is to be given to patients receiving oral anticoagulants the dosages of the
tter should be recalibrated. Side effects and adverse reactions: occasionally an
npleasant taste, furred tongue, nausea, vomiting (very rarely), gastro-intestinal
isturbance. Drowsiness, dizziness, headache, ataxia, skin rashes, pruritus,
nco-ordination of movement, darkening of the urine very rarely. During intensive
nd/or prolonged therapy, peripheral neuropathy has been reported. A moderate
eucopenia has been reported but the white cell count has always returned to

seizures in a few patients undergoing intensive, high-dosage metronidazole radiosensitization therapy.

Benign Breast Disorders

3 studies on Danol

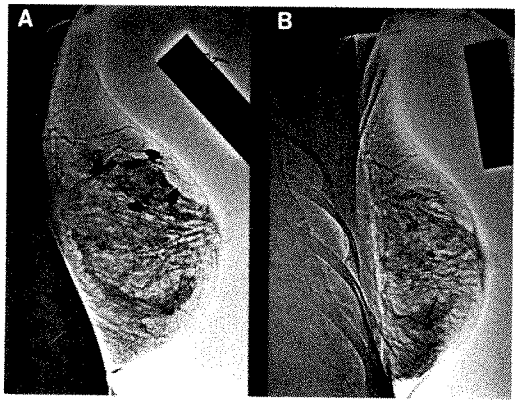
1. "...a marked improvement in both objective and subjective symptoms in 87.5% of patients studied."

(Study of 40 patients given Danol for up to 6 months. Obstet. Gynec. 1976, 48: 93.)

---

2. 75.8% "...experienced complete relief of subjective discomfort with disappearance of clinical signs."

(Study of 58 patients given Danol for between 74 and 310 days. Am. J. Obstet. Gynec. 1977, 127: 130.)



Xeromammograms of patient with intense fibrocystic disease (A) showing marked reduction in breast size and cystic area (B) after 6 months on Danol.

---

3. "...a significant decrease and elimination of breast pain and tenderness ...and elimination of nodules and lumpy areas..."

(Preliminary report on open study of 260 patients given Danol for 4 to 6 months. J. int. med. Res. 1977, 5 (Suppl. 3) 101-108.)

Danol
danazol

antigonadotrophic agent without oestrogenic or progestogenic activity

Danol (danazol 200 mg) PL 0071/0095. Bottles of 100 capsules. Basic NHS cost of one day's treatment £1.42 (3 capsules). **Danol-½** (danazol 100 mg) PL 0071/0094. Bottles of 100 capsules. Basic NHS cost of one day's treatment 72p (3 capsules). **Dosage** Adults 200-800 mg daily. See Data Sheet for details. **Contra-indications** Pregnancy. **Precautions** 1. Because of fluid retention, use with care in patients with cardiac or renal dysfunction, epilepsy or migraine. 2. In hepatic dysfunction. 3. Danol may potentiate the action of anticoagulants. 4. Discontinue if signs of virilisation develop. **Side Effects** Androgenic side effects (acne, oily skin, fluid retention, hirsutism, clitoral hypertrophy, voice changes, flushing and reduction in breast size) occur occasionally. Nausea, headache, dizziness, rash, nervousness, vertigo, emotional lability, backache, skeletal muscle spasm and hair loss have also been reported. Danazol has little overall effect on libido and thrombo-embolic complications have not been reported. Any increase in weight which occurs may respond to dietary control. Danol is a trade mark. Clinical reports and full prescribing information available on request from **Winthrop Laboratories,**
Surbiton-upon-Thames, Surrey.

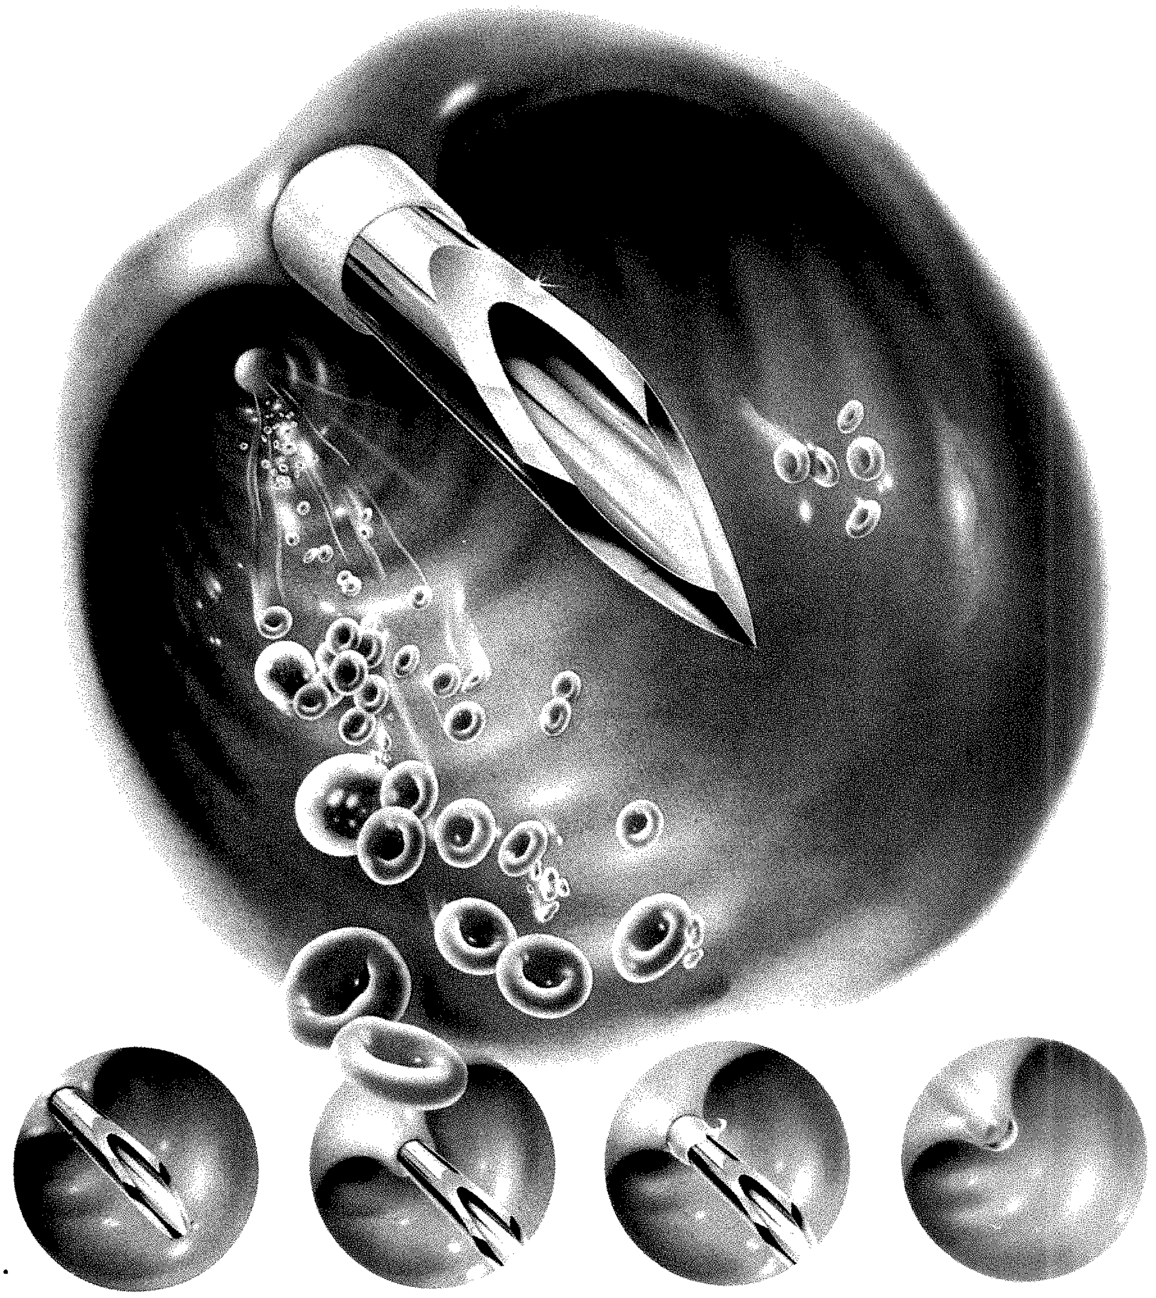
The intravenous difference



Where the distance between the cannula tip and the heel of the needle bevel is too great, there is a risk of piercing the opposite vein wall before the cannula is satisfactorily placed within the lumen. With Abbocath®-T the cannula tip fits snugly behind the heel of the short bevelled needle tip.

An abrupt cannula shoulder requires a high penetration force, leading to tissue and vein trauma, discomfort, and repeat procedures. The electronically formed double-taper tip of Abbocath-T requires a minimal penetration force which is constant from cannula to cannula.

A thin cannula shoulder is likely to curl back or shear during insertion, irritating the vein intima and increasing the risk of thrombus formation and phlebitis. The Abbocath-T cannula tip is smooth and sturdy, with no ragged edges or thin spots, and never protrudes over the heel of the needle.

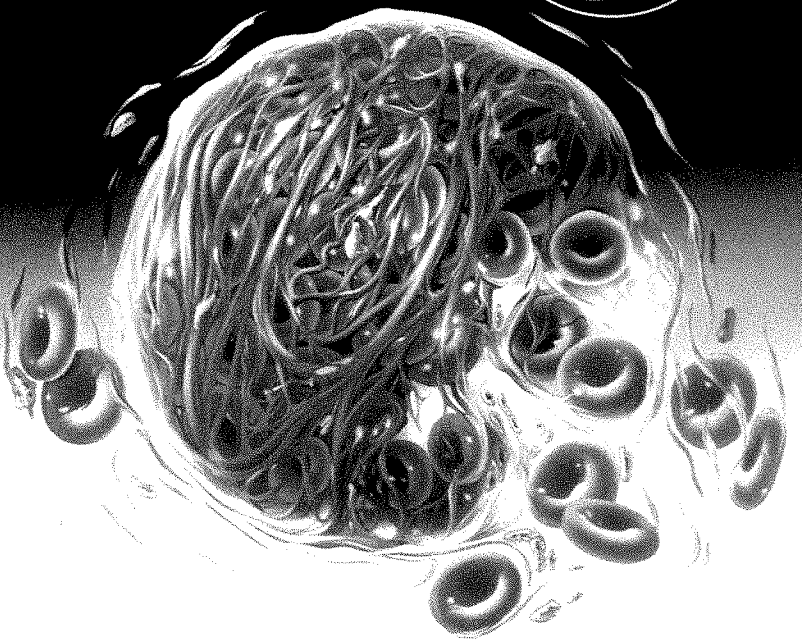
Announcing the availability of

ABBOKINASE®
urokinase for injection



The first tissue-culture urokinase for the treatment of pulmonary embolism.

With significant advantages, both clinical and practical, over other thrombolytics, anticoagulant therapy and surgery.

- Abbokinase achieves rapid clot lysis by a direct action on the fibrinolytic mechanism. Urokinase has a greater affinity for plasminogen within the formed clot (gel phase plasminogen) than for circulating plasminogen (sol phase plasminogen)[1] and is therefore the most selective thrombolytic agent in current use.[2]
- Abbokinase is devoid of antigenic activity in humans – unlike streptokinase. This obviates prior antibody testing and the need for corticosteroids for the prevention and alleviation of allergic response.[3]
- Abbokinase is more successful than anticoagulants which do not lyse the clot or reopen the vessel.[4,5]
- Abbokinase is more economical and less traumatic than surgery.

Data sheet information **Presentation** Abbokinase is available in 10ml vials containing 250,000iu of a highly purified sterile lyophilised formulation of urokinase obtained from cultures of human kidney cells. Urokinase plasminogen activator excreted in the urine of normal healthy individuals. When reconstituted with 5.2ml distilled water according to directions each ml of isotonic solution will contain 50,000iu urokinase 5mg mannitol 9mg sodium chloride. **Uses** Abbokinase in vivo and in vitro produces the release of plasmin by an enzymatic action on human plasminogen. Abbokinase has only minimal activity in reducing fibrinogen levels but bloo plasminogen levels are reduced, the effect being dose-dependent. Abbokinase is virtually non-antigenic to humans and, in therapeutic doses, is thromboplastin-free. Thrombolytic therapy is indicated in the treatment vascular occlusions caused by forming or recently formed fibrin clots. Theoretically the best results will be obtained with thrombi less than 24 hours old. Abbokinase is indicated as a thrombolytic agent in pulmona embolism **Dosage and Administration** Abbokinase is administered intravenously by continuous infusion, usually for a period of 12 hours. It is recommended that Abbokinase be given in a solution of Normal Saline by consta infusion. An initial loading dose to be given during the first ten minutes of therapy is advocated. This loading dose should be equal to the amount which it is planned to administer over each succeeding period of one hour. Ideal an infusion pump should be used to maintain a constant rate of infusion. Abbokinase is reconstituted with 5.2ml sterile water for injection, without preservatives. For administration the reconstituted solution should be furth diluted with normal saline to the total volume of solution (195ml) for a 12 hour treatment including the priming dose. From this solution, 15ml are given over a period of 10 minutes as the priming dose and the remainder ove period of 12 hours at the rate of 15ml/hour. Dosage: It should be noted that patient-to-patient variation in response can be expected, due to individual variation in levels on inhibitory factors. Certain disease states such uraemia, some malignancies and dyslipidaemias can be associated with an increased plasma level of urokinase or plasmin inhibitors. In other conditions such as massive pulmonary embolism, endogenous fibrinolyt activity may be increased. The recommended dosage regimen for the treatment of pulmonary embolism is: Loading dose 4,400iu per kg bodyweight over 10 minutes. Constant infusion dose 4,400iu per kg bodyweight p hour. Duration of infusion, 12 hours. **Contra-indications, Warnings, etc.** Contra-indications Manifest or recent (i.e. within 3 days) haemorrhage. Any haemorrhagic diathesis. Severe hypertension. During cardiopulmona resuscitation. During pregnancy or suspected pregnancy. Warnings and Precautions The major adverse effect of Abbokinase is haemorrhage, usually associated with too high dosage. A high incidence of bleeding fro minor skin lesions, therapeutic and diagnostic puncture sites and pre-existing gastro-intestinal lesions has been observed with high dosages. Any evidence of significant internal bleeding necessitates the cessation thrombolytic therapy. An anti-fibrinolytic agent such as epsilonaminocaproic acid (EACA) may be used as an antidote if required. Epsilonaminocaproic acid should be available for use, if necessary, during infusions wi Abbokinase when high doses are being administered. Post-partum for one month. Recent surgery (within 3 days). Concurrent anti-coagulant therapy should be administered cautiously. Mild temperature increases have been observed during thrombolytic therapy with Abbokinase. When there is a history of hypersensitivity to drugs etc., caution is advised and facilities as well as corticosteroids, adrenaline, etc. should be readily available when Abbokinase is infused. Monitoring The monitoring of fibrinolytic activity and of plasminogen levels is desirable. Pharmaceutical Precautions: The lyophilised powder should be stored at 2-8°C. Reconstituted solution should be used immediately after mixing and secondary dilution. **Legal Category** POM **Package Quantities** Available in packs of 2 vials of 250,000iu each (List No. 6109). **Further Information** The potency of Abbokinase is expressed in International Units (iu). For practical purposes the iu is considered by most authorities to be equivalent to the CTA unit. The Ploug unit is usually considered to be equal to 1.4iu. **Product Licence Number** 0037/0096 **References** 1. Kakkar VV, Scully MF. Thrombolytic therapy. *Brit Med. Starvation is staring you in the face

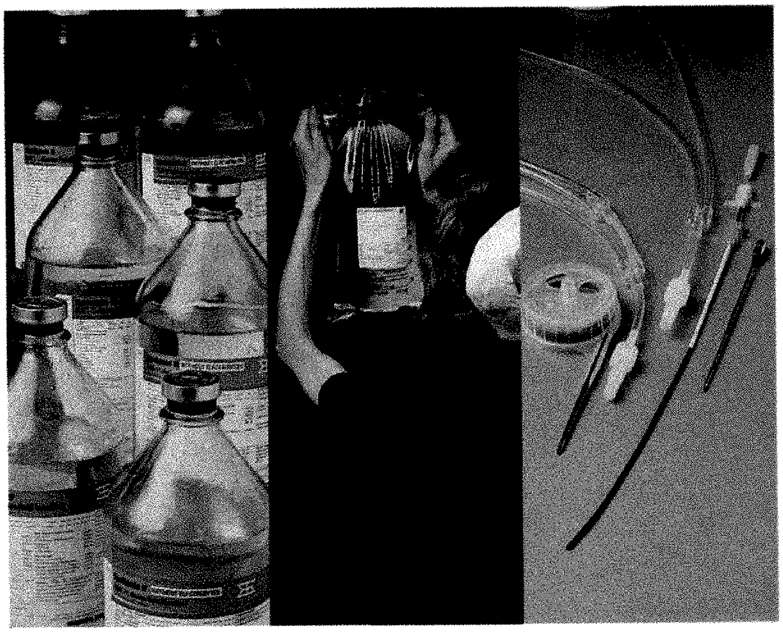
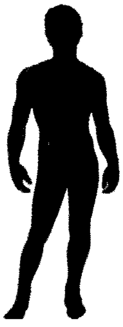
Patients with protein calorie malnutrition are essentially starving patients. They urgently need nutritional support and, when gastrointestinal function is impaired or absent, parenteral nutrition is the only practical way to provide it. For these patients, Travenol has the sensible answer: an integrated, effective[1], parenteral nutrition system. It includes Synthamin amino acid solutions. Calorie sources. Electrolytes. Peripheral and central venous catheters. Specially designed sets. And 3-litre Viaflex® containers for the sterile compounding of regimens in pharmacy and non-air-dependent administration on the ward.

Travenol has the sensible answer to parenteral nutrition – because Travenol thinks things through.





Travenol makes sense of Parenteral Nutrition

Synthamin

amino acid injections

Presentation
Synthamin injections are sterile, non-pyrogenic solutions of essential and non-essential L-amino acids provided with or without electrolytes. Synthamin 7S also provides calories as Sorbitol.

Indications
Parenteral nutrition.

Administration and Dosage
For intravenous administration. An associated source of non-protein energy should be administered of not less than 0.75MJ (180Cal.) per gram of nitrogen administered. Dosage depends on patient's metabolic requirements and clinical response.

Contra-indications
Severe liver disease. Solutions with electrolytes are contra-indicated in renal failure.

Precautions
As with all hypertonic solutions, vein irritation may occur. Do not administer unless the solution is clear and container undamaged.

Availability

Synthamin 7S (PL 0116/0043) 500ml £4.83.
Synthamin 9 (PL 0116/0054) 500ml £6.00.
Synthamin 9 without electrolytes (PL 0116/0067) 500ml £5.65.
Synthamin 14 (PL 0116/0055) 500ml £8.00.
Synthamin 14 without electrolytes (PL 0116/0068) 500ml £7.65.
Synthamin 17 (PL 0116/0056) 500ml £9.80.
Synthamin 17 without electrolytes (PL 0116/0069) 500ml £9.45.

Blood transfusion and renal transplantation

G. PROUD, B. K. SHENTON AND B. M. SMITH*

SUMMARY

Blood transfusions given to potential renal transplant recipients are beneficial to subsequent graft survival. This study has shown an association between the inhibitory activity of patients' plasma on their own non-specific lymphocyte responses to antigen and the administration of blood transfusions. Most of the inhibitory activity was related to alpha-2 macroglobulin. Alpha-2 macroglobulin was able to prolong the survival of rat cardiac allografts. Immunoregulatory activity related to the alpha globulins of plasma has been described in a wide variety of conditions (i.e. cancer, pregnancy, diabetes) and this study has shown similar activity following blood transfusions.

REPORTS from Los Angeles (Opelz et al., 1973) and Newcastle (Murray et al., 1974) first drew attention to the possible beneficial effects on renal transplant recipients of blood transfusions administered prior to transplantation. Since then, most transplantation centres throughout the world have found an association between blood transfusions given before transplantation and improved graft survival. Uldall et al. (1977) updated the Newcastle results and confirmed the original findings of improved graft survival when blood transfusions had been given prior to transplantation.

The latest analysis of our results in 274 consecutive first cadaver allografts performed between October 1969 and December 1977 is shown in *Fig.* 1. The results were analysed by comparing renal transplant recipients who had received blood transfusions prior to transplantation, with those who had not, in two ways. First, all graft failures were included, and then non-immunological failures were excluded. The results were assessed by the actuarial method of Barnes (1965). Regardless of whether non-immunological failures were excluded or not, those patients who had received blood transfusions prior to transplantation were at less risk from graft loss than non-transfused patients. The improved graft survival was still apparent at the 6-year follow-up in the transfused patients, though at this stage only a comparatively few patients were under review and statistical significance between the groups was no longer apparent.

A median of 5 units of whole blood or packed cells had been transfused to the patients studied. The amount of blood transfused had no effect on subsequent graft survival, two or three units having the same effect as many.

The reasons for improved graft survival following transfusion are not known (Perkins, 1977; Persijn et al., 1977). We have studied *in vitro* the ability of plasma to regulate non-specific lymphocyte reactions with antigen, and have identified some of the plasma factors which may be responsible for the transfusion-induced suppression.

Patients and methods

Four patient groups were studied: (i) normal subjects—non-transfused (normal); (ii) renal failure patients—non-transfused (renal 0); (iii) renal failure patients—multi(10)-transfused (renal multi) and (iv) haemophiliacs—multi(10)-transfused (haemophiliacs).

Renal patients had never been transplanted, and all required dialysis. Transfused renal patients had been on dialysis for a longer period than non-transfused patients. Fehrman et al. (1978) report that improved graft survival is linked more strongly to pre-transplant dialysis than to blood transfusion. To control any possible immunological effects of dialysis a group of multi-transfused haemophiliac patients was also studied.

The non-specific lymphocyte inhibitory activity of plasma was studied by measuring the ability of each patient's plasma to inhibit the response of both allogeneic and autologous lymphocytes to PPD antigen (purified protein derivative of mycobacterium tuberculosis). The inhibitory activity of plasma was measured using the tanned erythrocyte electrophoretic mobility (TEEM) test (Shenton et al., 1978). This is an electrophoretic technique for measuring changes in cell-mediated immune responses and depends upon the production of a lymphokine from stimulated lymphocytes, termed electrophoretic slowing factor, which reduces the mobility of tanned sheep red blood cells in an electrophoretic field. The lymphokine alters the surface electrical charge on the tanned sheep red cells and thus alters their mobility when this is measured in the electric field of a Zeiss cytopherometer. Test plasma samples were diluted (1/60, 1/120, 1/140 etc.) in Hanks's balanced salt solution, and the dilution of plasma producing 50 per cent inhibition of the lymphocyte response to PPD (determined from graphically expressed results) was taken as a standard. All tests were performed on fresh plasma, which was obtained from heparinized venous blood. The ability of each plasma to inhibit the response of lymphocytes to PPD was measured against both allogeneic lymphocytes, obtained from normal adult volunteers, and autologous lymphocytes from the patient's own blood.

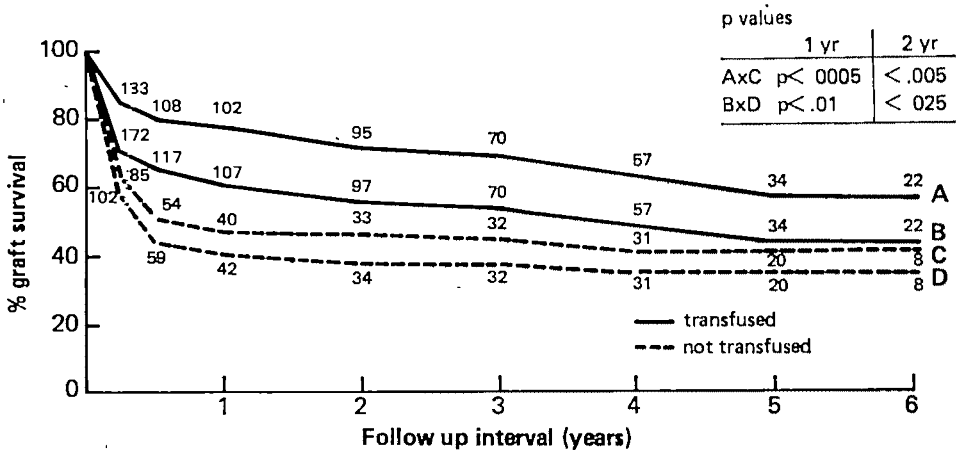

Fig. 1. Effect of prior blood transfusion on 274 consecutive first cadaver renal allografts (including 56 non-immunological failures). A+C: non-immunological failures excluded; B+D: all failures.

Lymphocytes were obtained from peripheral blood by the one-stage sodium metrizoate technique, 'Lymphoprep' (Bøyum, 1968) and were thoroughly washed three times in Hanks's balanced salt solution before use. The lymphocytotoxicity of each plasma sample was assessed on allogeneic lymphocytes by the method described by Dewar and Murray (1976) and on the lymphocytes used in the test.

Statistical methods

The inhibitory activity of plasma and plasma fractions on lymphocyte responses to antigen (*Tables I, II* and *III*) was compared between groups using Student's *t* test analysis, and the same test was used for comparing plasma alpha-2 macroglobulin concentration (*Table IV*). Cardiac allograft survival following macroglobulin therapy (*Table V*) was evaluated using Student's *t* test analysis as shown, and was also studied using the non-parametric rank test of Wilcoxon when the statistical significance between groups was the same as with the *t* test. Renal graft survival was assessed by the actuarial method of Barnes (1965).

Results

Inhibitory activity of whole plasma

The concentrations and dilutions of plasma producing 50 per cent inhibition of the lymphocyte response to antigen are shown in *Table I*. In renal patients, the inhibitory activity of plasma from transfused patients against allogeneic lymphocytes was much greater than plasma from non-transfused patients, 50 per cent inhibition of the lymphocyte responses occurring at a dilution of 1/1470 compared with 1/119 in the non-transfused patients ($P<0·01$). Similarly, the inhibitory activity of plasma from haemophiliacs was much greater (50 per cent inhibition occurring at a plasma dilution of 1/1170) compared with normal subjects (1/75; $P<0·01$). There was no difference in the inhibitory activity on allogeneic lymphocytes of plasma from each transfused group ($P=0·112$). Equally, there was a significant rise in the inhibitory activity of plasma against autologous lymphocytes in the transfused patients (renal multi—50 per cent inhibition occurred at a dilution of 1/556 compared with renal 0—1/119, $P<0·01$; and haemophiliacs—1/849 compared with normal—1/93, $P<0·01$). Haemophiliac patients showed greater autologous lymphocyte inhibitory activity than transfused renal patients, suggesting that the inhibitory activity was more likely to be due to transfusion than some effect of dialysis.

Inhibitory activity of fractionated plasma

To study the fractions of plasma responsible for the raised lymphocyte inhibitory activity, 2-ml plasma samples were subjected to gel filtration on G200 Sephadex (Ford et al., 1973). The column used was 1 × 30 cm and the running buffer 0·01 M phosphate buffered saline, pH 7·2, set at a flow rate of 18 ml/h. The protein concentration of the eluted fractions was determined spectrophotometrically (280 nm absorption using the Uvicord LKB analyser) and the pattern of protein elution was identified with fused rocket electrophoresis (Weeke, 1973). The antibody to

human plasma proteins was prepared in the rabbit and supplied by Mercia Diagnostics Limited. Eluted fractions were collected and pooled into four aliquots according to the main protein peaks (Ford et al., 1973): peak 1 (macroglobulins); peak 2 (γ-globulin); peak 3 (albumin); peak 4 (low molecular weight). The inhibitory activity of each pooled aliquot was determined using both allogeneic and autologous lymphocytes. A summary of the inhibitory activity is shown in *Table II*. In normal subjects all the lymphocyte inhibitory activity was confined to peak 1. Non-transfused renal patients showed activity in peak 1 and peak 4 and in transfused renal patients the lymphocyte inhibitory activity in both peak 1 and peak 4 rose significantly ($P<0{\cdot}01$) when tested with both allogeneic and autologous lymphocytes compared with non-transfused renal patients. In both transfused groups inhibitory activity was noted in peak 2 against allogeneic lymphocytes only. Haemophiliacs showed significantly greater peak 1 activity than did normal subjects ($P<0{\cdot}01$), though, unlike renal patients, no peak 4 activity was measurable.

Thus, much of the inhibitory activity appeared to lie in peak 1, the macroglobulin peak, especially against autologous lymphocytes. In recent years, there has been much interest in the immunoregulatory activity of plasma macroglobulins, particularly alpha-2 macroglobulin (Cooperband et al., 1976; Davis et al., 1978; Stein-Streilein and Hart, 1978), and, for this reason, the effect on the inhibitory activity of removing alpha-2 macroglobulin from plasma was studied using immuno-adsorbent chromatography.

Immuno-adsorbent chromatography for alpha-2 macroglobulin

Alpha-2 macroglobulin (α2M) was removed from plasma by immuno-adsorbent chromatography utilizing rabbit anti-human α2M conjugated sepharose 4B (McEntire, 1978). Two sepharose columns were set up in 5 ml blood syringes; in one, rabbit anti-human α2M was conjugated to the sepharose and in the other (the control column) normal rabbit serum was conjugated. One millilitre of fresh plasma was divided into $2 \times 0{\cdot}5$ ml samples and each was applied to, incubated with and then washed through either the anti-α2M column or the control column. The concentration of α2M was determined before and after each column run using rocket electrophoresis (Axelsen et al., 1973). Similarly, the lymphocyte inhibitory activity of each plasma was assessed before and after each column run against allogeneic and autologous lymphocytes, the post-column values being corrected back to the original volume and dilutions of plasma.

^{125}I-labelled IgG was eluted from both columns to check that non-specific binding of protein to the conjugated sepharose was not occurring. The recovery rate of IgG from both columns was greater than 95 per cent.

Plasma samples were then passed through the columns. In the elutions from the anti-α2M column, α2M could not be detected using rocket electrophoresis, whereas there was a greater than 90 per cent recovery from the control column.

The inhibitory activity of plasma on allogeneic and autologous lymphocytes before and after each column run is shown in *Table III*. Elutions from the control column showed little change in inhibitory activity compared with pre-column values against either allogeneic or autologous lymphocytes. However, there was a very significant reduction in the inhibitory activity of plasma eluted from the anti-α2M column on allogeneic and autologous lymphocyte responses to PPD.

Thus the removal of α2M from plasma was associated with a large fall in the inhibitory activity of plasma. The inhibitory activity of plasma was not related to the concentration of α2M (*Table IV*) determined by rocket electrophoresis. Only in the haemophiliac patients was a slight rise in the α2M concentration noted.

Throughout this investigation, lymphocytotoxicity of test plasma samples on allogeneic cells was not detected.

Evaluation of alpha-2 macroglobulin in the rat

Attempts to prolong allografts in rodents using human α2M have met with mixed success in the past. Kamrin (1959) and Mowbray (1963a) were successful in prolonging graft survival, whereas Davis and Boxer (1965) failed.

To evaluate α2M, the heterotopic cardiac allograft model in inbred rats (described by Ono and Lindsey, 1969) was used (heart donor PVG/C—serotype AgB5; recipient WAG—serotype AgB2). α2M, prepared from Cohn fraction IV of pooled normal human plasma (Ford et al., 1973), was given to the recipient in two 25 mg i.v. doses, the first 24 h prior to transplantation and the second 24 h after transplantation. The results are shown in *Table V*. Following macroglobulin therapy, a mean graft survival time of 10·6 days was achieved compared with 7·3 days in untreated rats and 7·2 days in rats receiving 25 mg human albumin i.v. 24 h before and 24 h after transplantation. This prolongation of graft survival was highly significant. In the control groups no rat heart graft survived beyond 8 days compared with a minimum survival of 9 days in the macroglobulin-treated rats.

Discussion

Kamrin (1959) was the first to draw attention to the immunosuppressive properties of α2M by demonstrating prolonged skin allograft survival in rats following its administration. Mowbray (1963a) successfully repeated this work, and suggested (Mowbray, 1963b) that it was effective in the inductive phase of antibody production. As previously noted, not all workers were successful (Davis and Boxer, 1965). However, following work by Mannick and Schmid (1967), who prolonged skin allograft survival in mice following α2M therapy, the immunosuppressive properties of naturally occurring plasma proteins, in particular the α-globulins and glycoproteins including α2M, have been described in a wide variety of conditions. Some of these are pregnancy (Gaugas, 1974), cancer (Glasgow et al., 1974) and transplantation (Riggio et al., 1969). Cooperband et al. (1976) extensively reviewed these apparently non-antigen-related immunosuppressive factors. Some recent work has suggested that plasma glycoproteins may induce the lymphocyte hyporesponsiveness and insulin resistance which is seen in diabetics who become pregnant or develop cancer (Davis et al., 1978).

This study has shown that plasma from transfused patients showed a much greater ability to inhibit the responses of allogeneic and autologous lymphocytes to the non-specific antigen PPD. All the allogeneic lymphocytes came from persons known to respond to tuberculin. Less was known of the renal patients. It was regarded as unethical that patients who might shortly receive a transplant should be skin tested. Equally, the interpretation of skin testing in renal patients might be difficult as it is well known that uraemic patients possess a degree of cellular anergy (Roitt, 1977). However, all the patients came from the local population, the large majority of whom are sensitized to tuberculin.

When plasma was fractionated on G200 Sephadex much of the lymphocyte inhibitory activity was found in the macroglobulin region in both transfused and non-transfused patients. The inhibitory activity in the macroglobulin fraction was much greater in the transfused patients.

Removing α2M from plasma by immuno-adsorbent chromatography resulted in a very significant fall in the inhibitory activity to both allogeneic and autologous lymphocytes (*Table III*). Any residual activity was presumably due to either γ-globulin, or, in the case of renal patients, to the low molecular weight fraction, peak 4. Against autologous lymphocytes it is likely that the residual activity seen in the plasma from renal patients is due only to the low molecular weight fraction, as no γ-globulin activity was detected (*Table II*). The low molecular weight fraction has yet to be fully characterized.

Cellular anergy in uraemic patients has already been referred to. In a study to be reported shortly (Proud, 1979), the cellular anergy has been shown to be a separate factor from the lymphocyte inhibitory activity of plasma in both transfused and non-transfused renal patients.

Immunosuppressive activity of the alpha globulin is not species specific (Stein-Streilein and Hart, 1978). Thus, the demonstration of the ability of α2M to prolong cardiac allograft survival in rats is an indication of the important immunoregulatory activity it exhibits. The rise in lymphocyte inhibitory activity of plasma following transfusions related to α2M might offer an explanation for the subsequent renal allograft survival seen in these patients.

Whilst the inhibitory activity of plasma rose following transfusions, an increase in the concentration of α2M did not necessarily follow. Glasgow et al. (1974) and others have reported that an immunosuppressive low molecular weight peptide that is recoverable from α-globulins is present in greater concentration in cancer patients. Some early work in our own laboratory has suggested that a low molecular weight peptide can be recovered in greater quantity by dialysis from transfused renal and haemophiliac patients. α2M may be acting as a carrier protein for an active low molecular weight fraction which could be lymphocyte-derived.

A prospective study is being carried out to determine whether the lymphocyte inhibitory activity of plasma, as described in this paper, is of prognostic value in clinical transplantation when measured in the recipient immediately prior to receiving a renal allograft. It is too early to draw any conclusions. However, we have studied plasma obtained from a series of consecutive renal transplant recipients immediately prior to transplantation 5 years ago, and since stored at −20 °C. Whilst recognizing that the inhibitory activity of plasma falls slowly with storage, a significant correlation was found between lymphocyte inhibitory activity of plasma and graft survival. Greater lymphocyte inhibitory activity was associated with improved graft survival (Shenton, 1979).

Shumway and his colleagues (Coulson et al., 1976) suggested that naturally occurring immunosuppressive proteins could be used therapeutically. If the prospective studies confirm the findings described here, the use of alpha-2 macroglobulin in the treatment protocol of renal transplant recipients will need to be assessed.

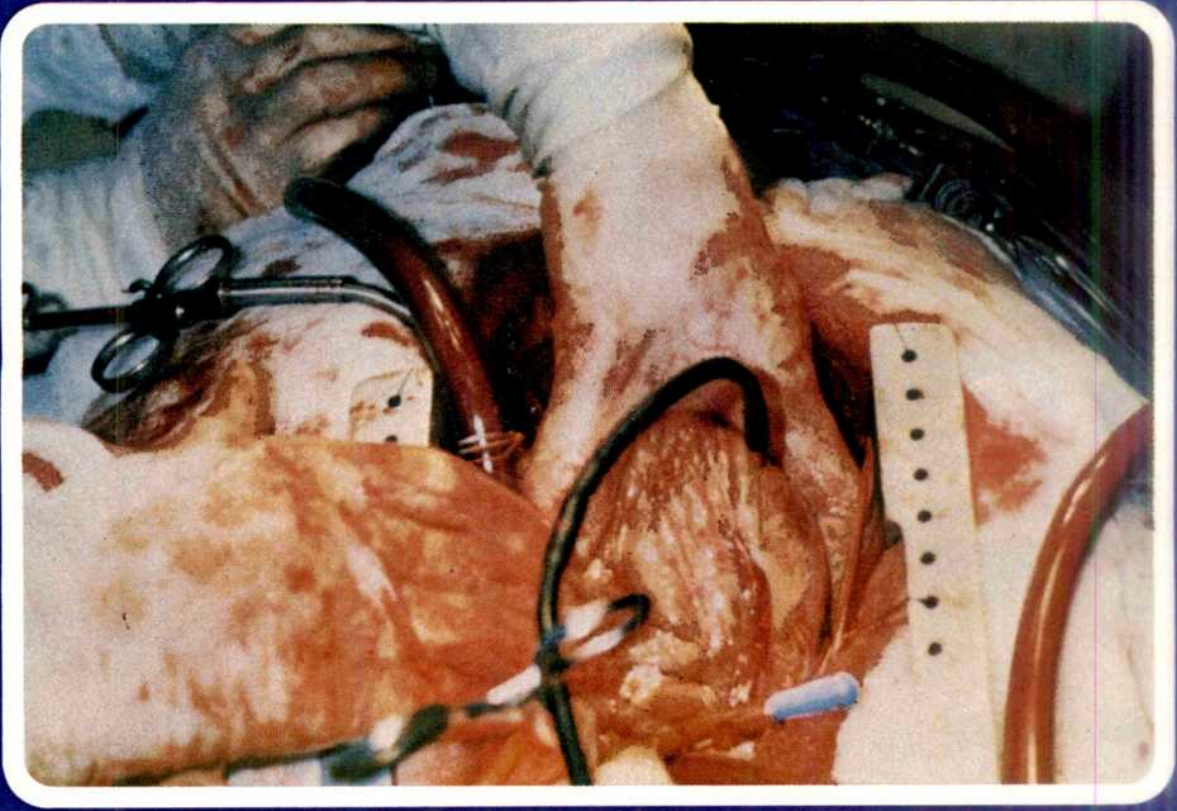
Magnapen

ampicillin/flucloxacillin



Reliable antibiotic cover for the at-risk patient.

In cardiothoracic surgery, infection poses a special threat. It is essential to reduce the risk to an absolute minimum with prophylactic antibiotic cover[1].

Magnapen is of proven value in prophylaxis. In a recent study of 221 patients undergoing thoracotomy for lung resection[2] of whom 181 received Magnapen cover, the author concluded that "There was a significantly reduced incidence of pneumonectomy space infection, post-operative pneumonia and wound infection after pneumonectomy and lobectomy in those patients receiving prophylactic antibiotics compared with those not receiving prophylactic antibiotics."

Magnapen combines the broad spectrum of ampicillin with the anti-staphylococcal activity of flucloxacillin. It can thus be relied on to eliminate virtually all strains of staphylococci[3,4], Strep. viridans[5] and other likely wound pathogens.

Prescribing Information

Magnapen Capsules: Black and turquoise capsules overprinted "Magnapen" containing 250mg ampicillin as Ampicillin Trihydrate B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Magnapen Syrup: Bottles containing powder for the preparation of 100ml suspension. When reconstituted each 5ml contains 125mg ampicillin as Ampicillin Trihydrate B.P. with 125mg flucloxacillin as flucloxacillin sodium.
Magnapen Vials: Each vial contains 250mg ampicillin as Ampicillin Sodium B.P. with 250mg flucloxacillin as flucloxacillin sodium.
Uses: Severe infections. Post-operative chest and wound infections. Prophylaxis in major surgery.

Dosage: Adult: 1 capsule or 10ml syrup, or 1 vial qid. Children: 2-10 years: ½ adult dose. Under 2 years: ¼ adult dose. Ampiclox Neonatal (regd.) is recommended for the treatment of infections in neonates and premature babies. PL0038/5001, 5009.
Contra-indications: Penicillin hypersensitivity, ocular administration.
Side-effects: As with other penicillins. An erythematous rash may occasionally occur, as with ampicillin. The incidence of this rash is particularly high in patients with infectious mononucleosis. If a rash is reported, it is advisable to discontinue treatment.
Pharmaceutical Precautions: Magnapen solutions for injection should be used immediately. Consult product literature before using with intravenous fluids.

Basic N.H.S. Prices: (correct at time of printing: Feb 79).
Capsules: 500mg, £18.06 (100 capsule pack).
Syrup: 250 mg per 5 ml, £3.18 (100ml).
Vials: 500mg, £7.45 (10 vials).

Magnapen is available to hospitals on regional contract dependent upon estimated usage.

Further information on Magnapen is available on request to the company.

Magnapen, BRL and the Company logo are registered trade marks.

A GENTLER APPROACH TO THE TREATMENT OF BREAST CANCER

Too often, victims of breast cancer must also suffer the unpleasant side effects of combination cytotoxic chemotherapy.

'Nolvadex' offers a gentler alternative, particularly in post-menopausal women with predominantly soft-tissue disease or metastases. Up to 70% of such patients have responded to 'Nolvadex'[1] yet side effects of treatment are far fewer and much less distressing than with cytotoxic chemotherapy or with additive endocrine therapy.[2]

Moreover, a simple oral dosage means that patients may continue with 'Nolvadex' treatment in their own homes.

Breast cancer and prostaglandins: a new approach to treatment

D. J. LEAPER, B. T. FRENCH AND A. BENNETT*

SUMMARY

The effect of the non-steroidal inhibitor of prostaglandin synthesis, flurbiprofen, has been studied on a transplanted mouse mammary tumour of spontaneous origin. Daily administration of 2·5 mg/kg flurbiprofen significantly reduced the growth of this NC adenocarcinoma transplanted subcutaneously into the right flank of WHT/Ht mice. Histological examination showed that primary tumours excised at 3 weeks from treated mice tended to have a more prominent lymphocytic infiltration. There was a non-significant tendency for mice treated with flurbiprofen alone to survive longer after tumour excision and to develop less local metastases, although scar recurrences seemed unaffected. The effect of adjuvant chemotherapy and local radiotherapy on local metastases and survival time tended to be greater when flurbiprofen was also given. This work supports and extends the basis for prospective clinical trials to evaluate the role of prostaglandins in human cancer and the value of prostaglandin synthesis inhibitors in cancer therapy.

CANCER of the breast is the commonest neoplasm in women and carries a poor prognosis (World Health Statistics Report, Logan, 1975). Survival figures for so-called 'early' breast cancer have changed little between the report by Halsted in 1907 and a recent trial (Report on an International Multicentre Trial supported by the Cancer Research Campaign, 1976).

The prostaglandins and related substances can be formed throughout the body, and they contribute to various physiological and pathological processes, including several aspects of malignant disease. Animal (Humes and Strausser, 1974; Tashjian et al., 1974; Galasko and Bennett, 1976) and human (Bennett, Charlier et al., 1977; Bennett, del Tacca et al., 1977) tumours can synthesize relatively large amounts of prostaglandin-like material. The most aggressive human malignant breast tumours, as shown by spread to bone or by histological examination, yield the largest amounts of postglandin-like material during tumour homogenization (Bennett, Charlier et al., 1977). Furthermore, those patients whose tumours produce most prostaglandins die soonest of their disease (Bennett et al., 1979).

Experiments presented previously and in this study used a transplantable mouse tumour of low immunogenicity which originally arose spontaneously in mouse mammary gland (Hewitt et al., 1976). The tumour can synthesize large amounts of prostaglandin E_2-like material, as indicated by thin-layer chromatography and bioassay (Bennett et al., 1978). In previous experiments, flurbiprofen, a non-steroidal anti-inflammatory drug which inhibits prostaglandin synthesis, reduced primary tumour growth, increased survival time following tumour resection—provided that treatment was started just before tumour transplantation—and substantially reduced the size of established tumours when used in combination with radiotherapy with or without chemotherapy (Bennett et al., 1978, 1979; Leaper, Bennett, Charlier et al., 1978; Leaper, Bennett, Houghton et al., 1978). In this study we report the effects of a lower dose of flurbiprofen on primary tumour growth, response to conventional anti-cancer treatment and formation of local recurrences, and examine a possible mode of action of flurbiprofen.

F, Flurbiprofen-treated group; C, control (syrup) group.
Three tumours omitted because of inadequate histological preparation.

Materials and methods

NC carcinoma was injected subcutaneously into 112 WHT/Ht mice which were treated orally with drugs as described in our previously cited work. Half received vehicle alone (raspberry syrup BP) and half were given 2·5 mg/kg flurbiprofen daily. The primary tumours were excised with a narrow rim of tissue at 3 weeks under ether anaesthesia and weighed. Thirty-two tumours from each group were fixed in formalin and prepared for routine paraffin histological slides and stained with haematoxylin, eosin and van Gieson's stains. They were then assessed blindly for tumour grade (based on a scoring system described by Bloom and Richardson, 1957), lymphocytic infiltration, tumour necrosis and fibroblastic reaction (as slight, intermediate or prominent).

Groups of mice (7 male, 7 female originally, but there were 4 anaesthetic deaths and 3 subsequent early deaths with no signs of tumour) were then given the following treatment: local radiotherapy (500 rad on the seventh and fourteenth days after tumour excision), and/or adjuvant chemotherapy weekly for 6 weeks (0·15 mg/kg melphalan on the first to third day, and 0·2 mg/kg methotrexate on the first day of each week starting 1 week after tumour excision). The two largest diameters (L and W) of local metastases and scar recurrences, seen 1–2 weeks after tumour excision, were measured weekly and the volumes were calculated from the formula volume $= \pi W^2 L/6$. All mice were observed until they died of cancer or were humanely killed (Bennett et al., 1979).

Results

Primary tumours excised at 3 weeks were significantly smaller in the mice given flurbiprofen—0·12 g ± 0·02 (mean ± s.e.mean)—than in controls—0·22 g ± 0·02 ($P < 0{\cdot}001$, Student's t test).

The 64 tumours that were assessed histologically were all poorly differentiated, scoring between 7 and 9 (9 being the poorest grade on the scale). They showed

Table IV: SURVIVAL TIME IN THE EIGHT TREATMENT GROUPS

	Survival time (d)
Control	73 (67–90)
Flurbiprofen	77 (65–85)
Chemotherapy	76 (70–90)
Flur-chemo	78 (72–92)
Radiotherapy	73 (69–81)
Flur-radio	72 (68–85)
Chemo-radio	77 (71–86)
Flur-chemo-radio	82 (70–94)

Values for survival time are medians and semi-quartile ranges.

no significant differences between test and controls except that lymphocytic infiltration tended to be greater in the tumours from flurbiprofen-treated mice (Fisher's exact test, $0{\cdot}1 > P > 0{\cdot}05$) (*Table I*). Scar recurrences and local metastases, defined as satellite growths of tumour connected by invaded lymphatic vessels to a primary tumour or its scar, were easily measurable 4 weeks after primary tumour excision. The most striking findings were a consistently lower volume and an initial lower incidence of local metastases in mice treated with flurbiprofen plus radiotherapy plus chemotherapy (*Table II*). Compared with controls, no treatment had a significant effect on scar recurrences, but their incidence was higher in mice given all three treatments compared with radiotherapy plus chemotherapy ($P < 0{\cdot}05$ weeks 4–6, Mann–Whitney U test). When flurbiprofen groups are combined regardless of other treatment, these show a significantly lower incidence and volume of local metastases compared with controls (*Table III*), but scar recurrences tended to be larger.

Survival times after tumour excision tended to be longer in mice given combined radiotherapy and chemotherapy than in controls, and to be further increased with the addition of flurbiprofen, but these trends were not statistically significant ($P > 0{\cdot}1$, *Table IV*). Nine weeks after tumour excision less than one-third of the mice remained alive.

Discussion

Flurbiprofen 5 mg/kg daily given to WHT/Ht mice inhibits prostaglandin synthesis in NC primary tumours (Bennett et al., 1978, 1979; Leaper, Bennett, Charlier et al., 1978; Leaper, Bennett, Houghton et al., 1978). Indomethacin inhibits prostaglandin synthesis in other animal tumours (Tashjian et al., 1974; Galasko and Bennett, 1976), and also reduces primary tumour growth (Tashjian et al., 1973; Plescia et al., 1975). The current study has shown a halving of primary tumour weights at 3 weeks with flurbiprofen at half the previous dosage (Bennett et al., 1978, 1979; Leaper, Bennett, Houghton et al., 1978), but it did not cure the mice of cancer. Humes et al. (1974) found that indomethacin delayed the appearance of murine tumours induced by Moloney sarcoma virus, so that indomethacin in these animal tumours may be cytostatic but not cytotoxic. However, indomethacin frequently prevented the appearance of transplanted methylcholanthrene-induced tumours in the experiments of Lynch et al. (1978).

Low dose chemotherapy and radiotherapy were used in the present experiments to mimic their clinical adjunctive effect to surgery, at doses similar to those used in a current trial in patients with breast cancer (Murray et al., 1978). The dose of radiotherapy was also small, being towards the lower end of the range of accepted 'normal' dosage given prophylactically after mastectomy (Report on an International Multicentre Trial, 1976). In previous experiments 5 mg/kg flurbiprofen daily enhanced the effect of this low dose cancer therapy on the growth of NC primary tumours (Bennett et al., 1978, 1979; Leaper, Bennett, Houghton et al., 1978). Half this dose in the present study enhanced the effect of radiotherapy plus chemotherapy on the incidence and volume of local metastases, but had little effect on scar recurrence. Unfortunately, no studies were done to determine the ability of the lower dose of flurbiprofen to inhibit prostaglandin synthesis to an adequate extent or for an adequate period. This may also explain why, unlike our previous results, the prolongation of survival with flurbiprofen was not statistically significant.

In a previous paper (Bennett et al., 1979) we reported no effect of 5 mg/kg flurbiprofen on local metastases. However, in that work the metastases were measured at death and not at precise times after tumour excision. Since the flurbiprofen-treated mice lived longer, the local metastases had longer to develop.

All the NC tumours were poorly differentiated according to the Bloom and Richardson scoring system. Although the reduction of tumour growth was not clearly explained by the histological findings, flurbiprofen may have enhanced an immunological response. Alternatively, more lymphocytes may have been present because greater tumour necrosis was occurring. Bloom et al. (1970), in a large study of human breast cancer, showed that 10 per cent had an intense lymphocytic infiltration, and over a 20-year period women with tumours in this category fared better. Other evidence in mice (Plescia et al., 1975) indicates that indomethacin may reduce tumour growth by removing a prostaglandin-induced inhibition of the immune system, but this may be only part of the explanation (Humes et al., 1974) or possibly unrelated (Lynch et al., 1978).

Powles et al. (1978) have shown that flurbiprofen or indomethacin can restore the efficacy of chlorambucil in rats with tumours made resistant to the drug, and Berstock et al. (1979) have found that flurbiprofen increases the survival time of mice given chemotherapy following resection of their primary tumours. The human data cited in the introduction, and the evidence from these animal experiments, emphasize the potential value of studying prostaglandins in human tumours, and of evaluating by prospective trials the place in anti-cancer therapy of drugs which inhibit prostaglandin synthesis.

Radionuclide venography for the demonstration of the proximal deep venous system

P. G. BENTLEY AND V. V. KAKKAR*

SUMMARY

The majority of pulmonary emboli originate in the deep veins of the lower limb. Fatal emboli usually arise from thrombi that have extended into the femoral or iliac veins or lower inferior vena cava. It is often impossible to demonstrate this area, the proximal venous segment, using conventional ascending venography when there is deep venous occlusion.

The alternative methods available—retrograde, pertrochanteric and transfemoral venography—are invasive. Radionuclide venography (RNV) has been developed as a less invasive alternative. It has been found to be accurate in the proximal deep venous system when compared with conventional ascending venography, and in the presence of proximal occlusion it gives images unobtainable by other means. The radiation dose is extremely low and a perfusion lung scan is obtained without further injection of isotope. RNV appears to be the best method for monitoring the progress of thrombolytic therapy for major venous occlusion.

THE proximal venous segment includes the upper femoral, external and common iliac veins and the lower inferior vena cava. Most fatal pulmonary emboli arise from thromboses that have extended into this area from distal veins. In the presence of occlusion it is usually impossible to demonstrate the upper extent of thrombus using conventional ascending X-ray contrast venography. Alternative diagnostic procedures include retrograde, pertrochanteric and transfemoral venography, all of which are invasive and at times misleading. There is therefore a need for a simple, less invasive demonstration of the proximal venous segment, not only for the initial diagnosis but also to monitor subsequent therapy. To this end radionuclide venography (RNV) has been assessed by direct comparison with X-ray contrast venography.

Patients and methods

One hundred patients referred for venography and lung scintigraphy were studied. They included patients with acute symptoms or signs of thromboembolism or a positive fibrinogen uptake test, others undergoing assessment before varicose vein surgery and patients on treatment with anticoagulants or thrombolytic therapy. Radionuclide venography (RNV) and ascending X-ray contrast venography (XRV) were performed on the same day.

Ascending X-ray contrast venography was performed using the technique of Kakkar (1972) and radionuclide venography by the following method. The patients were examined supine on a mobile horizontal imaging table. Two 2·5-cm diameter pneumatic cuffs were applied to each leg, one just above the ankle and the other just above the knee, and connected to a bellows and pressure gauge. A cobalt-60 spot marker was placed in the midline between the legs at the level of the upper border of the patella, another just below the symphysis pubis and a third at the umbilicus. Imaging was carried out using a gamma camera (Searle Pho-Gamma III) fitted with a diverging collimator. It was found helpful to have a persistence oscilloscope linked to the camera to provide a continuous visual display of progress of the radionuclide. The pneumatic cuffs were inflated to 100–150 mmHg and a 21- or 23-gauge butterfly needle was inserted into a dorsal foot vein on each side. A three-way stopcock was connected to permit injection of radionuclide followed by a saline flush. The system was tested with saline at the beginning of each examination. The patient was then positioned for imaging of the calves, with the cobalt-60 marker between the patellas at the top of the field of view.

One mCi of $^{99}\text{Tc}^{m}$-macroaggregated albumin (MAA) was injected into each foot, followed by approximately 20 ml of saline flush. Imaging commenced and the passage of the radionuclide into the deep veins of the calf was followed on the persistence oscilloscope and recorded on Polaroid film. If necessary, each calf was gently compressed once to fill the popliteal vein. If poor calf filling was observed, additional saline was injected. Imaging was complete when 50 000 counts had accumulated. With the cuffs still inflated, the table was moved to position the patient's thighs in the field of the camera so that both cobalt-60 spot markers were in view at opposite ends of the field. Images were obtained of the femoral veins after a further injection into each foot of 1 mCi MAA. Then the patient was positioned with the camera over the pelvis and lower abdomen. The cuffs were released and, with a further 10 ml of saline flush and active ankle exercising, images of the iliac veins and inferior vena cava were obtained. Exercise continued until thirty dorsiflexions of the ankles had been performed. At this stage a persistence film of the calf region was obtained followed by similar films of the thighs and pelvis. Finally, a standard perfusion lung scan was obtained without further injection of isotope. The time taken for RNV was 15 min with an additional 15 min if a lung scan was required also. Results were available immediately on Polaroid film.

An immediate assessment of each test was made and recorded in the patient's case folder. Subsequently all films were reviewed in the absence of clinical details. A positive XRV was defined as a filling defect, present on at least two films, or an area of non-filling with collateral circulation.

A positive RNV was defined as an area of decreased radioactivity (filling defect) with or without collateral circulation; stasis of radioactivity below an obstruction or persistence of radioactivity after exercise (*Fig.* 1).

Table I: CORRELATION BETWEEN RNV AND XRV

		Overall		Calf		Thigh		Pelvis	
		XRV							
		+	–	+	–	+	–	+	–
RNV	+	68	32	59	32	18	2	17	0
	–	25	75	30	79	6	174	0	183

Results

The results are shown in *Table I.* There was an overall correlation between RNV and XRV of 71·5 per cent with 16 per cent false positive and 12·5 per cent false negative results from RNV. In the calf, there was a correlation of 69 per cent with 16 per cent false positive and 15 per cent false negative results. In the thigh, there was a correlation of 96 per cent with 1 per cent false positive and 3 per cent false negative results. In the pelvis there was 100 per cent correlation, although XRV was often unsatisfactory above the external iliac veins.

---

* Thrombosis Research Unit, King's College Hospital Medical School, London.

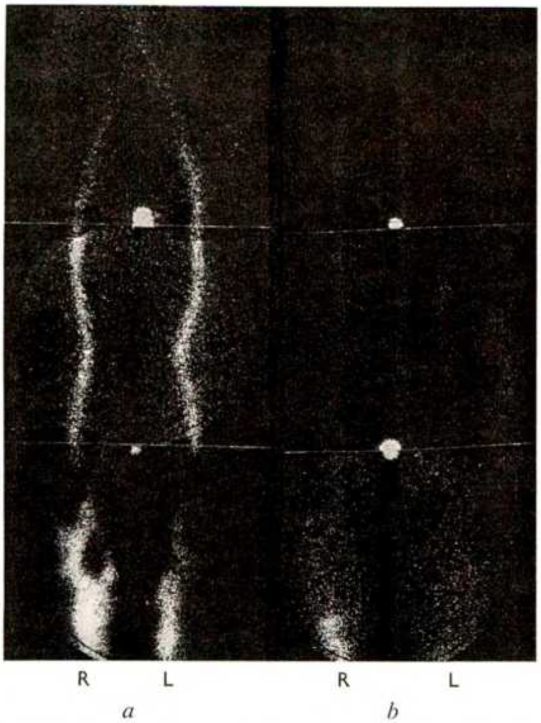

Fig. 1. Radionuclide venogram. *a*, Dynamic phase. There is a filling defect within the right calf. The remainder of the right side and the whole of the left side are normal. *b*, Static phase. There is persistence of radionuclide in the right calf distal to the filling defect.

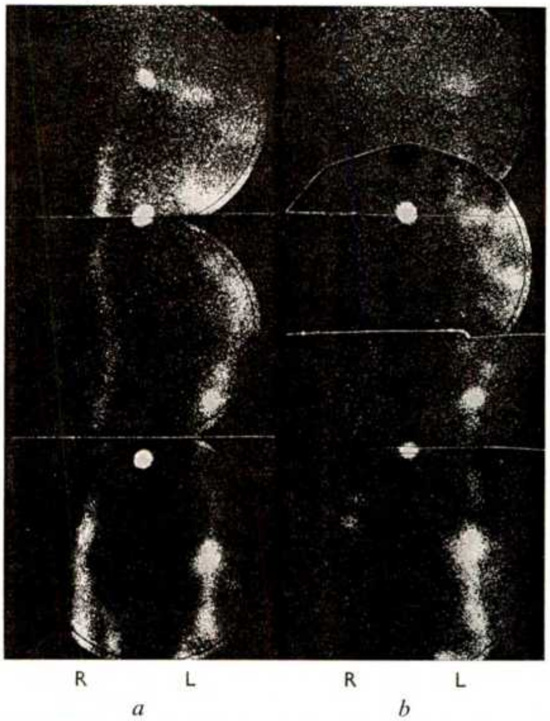

Fig. 2. Radionuclide venogram before thrombolytic therapy. *a*, Dynamic phase. The deep venous system on the left side is totally occluded up to the inferior vena cava with pooling of isotope in collateral circulation. The right side appears normal. *b*, Static phase. Radionuclide has cleared from the normal right side, but there is persistence on the left up to the level of the common iliac vein.

Minor thrombi in the calf (defined as those present in soleal veins alone or in tibial veins but less than 5 cm in length) were detected by RNV in 7 out of 13 cases (53·8 per cent) and larger calf thrombus in 20 out of 25 cases (80 per cent). In the femoral region 12 out of 13 (92 per cent) thrombi were detected. The one failure of RNV was a 5-cm non-occlusive thrombus localized to the lower femoral vein, with normal deep veins above and below it. In the proximal deep venous system RNV was positive in all 16 cases with occlusion shown on XRV. It gave a clearer outline of the iliac veins and lower vena cava than XRV, and in 11 cases showed more of the proximal venous segment than could be displayed by XRV. RNV was especially useful for monitoring the progress of thrombolytic therapy (*Figs.* 2–4).

Discussion

The use of isotopes for the demonstration of the venous system was first suggested following the chance observation of uptake of labelled macroaggregates of albumin in an area of thrombophlebitis in the arm of a patient undergoing lung scintigraphy (Webber et al., 1969). It was thought that the aggregates adhered directly to thrombus (Henkin et al., 1974) and that this effect could be reversed by heparin (Hayt et al., 1977). It is more likely, however, that persistence of radionuclide in the region of a thrombosis is due to stasis distal to the acute occlusion (Ryo et al., 1976).

The results presented in this study show that compared with XRV, RNV is progressively more accurate as imaging becomes proximal. This is emphasized in cases of proximal occlusion where RNV gives images unobtainable with conventional venography. Whereas diluted, slow moving X-ray contrast medium gives very poor resolution, no such disadvantage is seen with RNV. A slow transit time of radionuclide gives images of better definition and makes the test ideal for demonstrating the extent of occlusion where venous stasis and collateral circulation has occurred.

There is no ideal investigation for the diagnosis of acute deep vein thrombosis. The clinical features of this condition are notoriously confusing, with an accuracy of only 50 per cent when based on clinical examination alone (Lambie et al., 1970), and X-ray contrast venography remains the established diagnostic standard against which all other investigations must be compared. XRV is accurate and safe in the hands of those performing it regularly; however, it is invasive (Thomas, 1972) and there is a variable degree of discomfort for the patient together with a relatively high overall cost. Iodine sensitivity reactions may occur and the large hyperosmotic intravenous fluid load is undesirable in those patients with compromised cardiac function, although 60 per cent w/v contrast media (1480 mosmol/l) give less complications than the stronger solutions (Malins, 1978). The alternative, less invasive diagnostic procedures in common use are the fibrinogen uptake test, Doppler

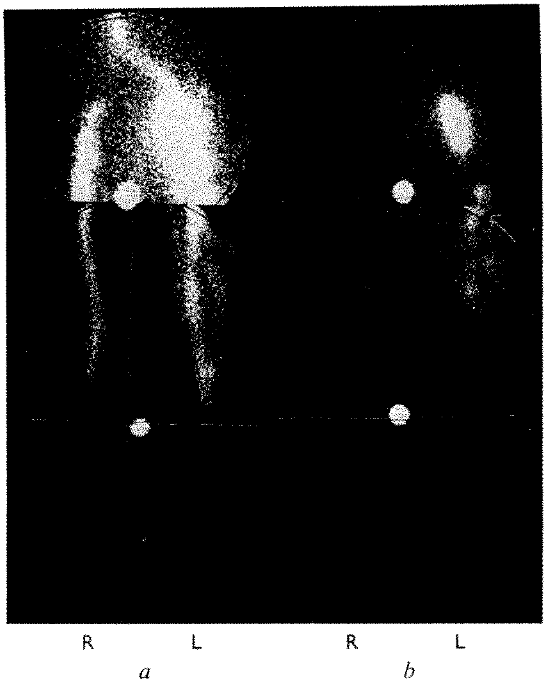

Fig. 3. Radionuclide venogram after 3 days' thrombolytic therapy. *a*, Dynamic phase. The left femoral vein is now partially open; radionuclide is trapped distal to the common iliac vein and reaches the inferior vena cava via a collateral. *b*, Static phase. Radionuclide persists on the left in the upper femoral and external iliac veins.

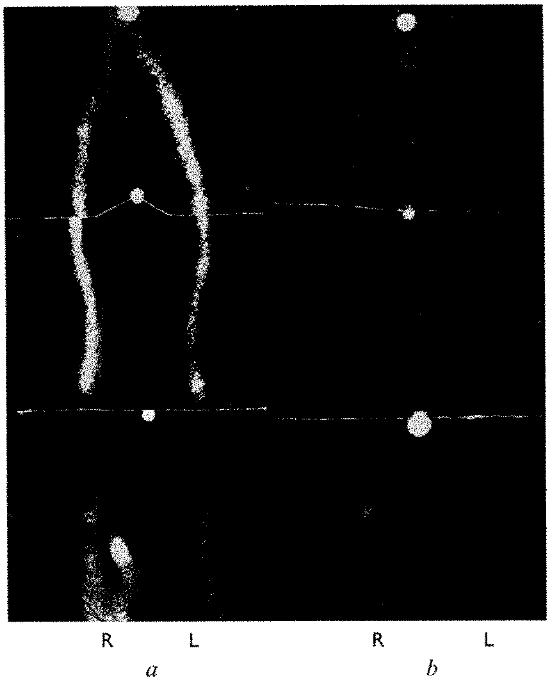

Fig. 4. Radionuclide venogram after 5 days' thrombolytic therapy. *a*, Dynamic phase. The major veins now appear normal, indicating lysis of all thrombus. *b*, Static phase. There is now no abnormal persistence of radionuclide.

ultrasound method and impedance phlebography. The former (Kakkar, 1972) is well suited to the screening of operative patients but requires at least 24 h before results are available, precluding its use as an urgent diagnostic method. In addition, it fails to give information about the deep venous system proximal to the inguinal ligaments (Browse, 1972), or to indicate the morphological extent of a thrombosis.

The Doppler ultrasound technique (Milne et al., 1971) detects only complete occlusions of the major veins and must be regarded as a crude screening test for massive thrombi. Impedance plethysmography shows promise as a useful screening test (Strandness and Sumner, 1972), but even if accurate will only serve to indicate those patients requiring venography.

RNV is certainly less invasive than conventional venography. Little expertise is necessary and apart from the insertion of a fine needle into a dorsal vein of each foot the investigation may be performed by non-medical personnel. The additional information obtained by the simple change of site of injection of isotope from an arm vein to dorsal foot veins suggests that RNV should be adopted in patients with suspected thromboembolism undergoing lung scintigraphy. The radiation dose from RNV appears to be very much less than that received during XRV. The lung radiation dose from RNV is 1·2 rad (ICRP, 1969) with an estimated fetal dose in a pregnant woman of 0·025 rad. The skin dose during XRV is 6 rad for the two abdominal films alone, with an estimated fetal dose of 1·2 rad. It would seem that with its specificity for the major veins of the pelvis, RNV should be well suited to use in suspected thromboembolism of pregnancy.

Because of inaccuracy in the calf, RNV will not yet replace XRV as the standard diagnostic procedure in suspected thromboembolism except in those centres with scanning facilities where XRV is not available. However, it is a useful addition to XRV in patients with major proximal venous occlusion where conventional venography is difficult and at times confusing and it appears to be the method of choice for monitoring the progress of thrombolytic therapy.

Acknowledgements

We thank the consultant staff of King's College Hospital for allowing us to investigate their patients and the King's College Hospital Voluntary Research Trust for financial assistance. We are grateful to Dr J. J. Barrett and Dr J. Laws for their constant encouragement during this study and would also like to acknowledge help given by several members of the Departments of Nuclear Medicine, Medical Physics and Radiology. We thank Mrs S. Docksey for typing the manuscript. This study was supported by the MRC programme, grant No. G937/756.

Statistics in *The British Journal of Surgery*

It is part of the clinical scientist's stock-in-trade to use statistical methods. In many instances, and by most readers, these can be taken on trust, but in that there is a wide variety of tests and, on occasion, disagreement amongst both amateurs and professionals on the best choice, it is always wise that authors quote the method used. It is indeed journal policy to quote methods, the reason for their choice and, in the case of clinical trials, the confidence or tolerance limits of the observed results. Delay in acceptance may occur if contributors do not include these details.

Nature of the disturbance in the body fluid compartments during and after surgical operations

W. M. ROBARTS*

SUMMARY

Haematocrit and plasma protein concentrations have been measured in patients undergoing surgical operations in order to estimate relative changes in the volumes of the extracellular and plasma compartments. That these provide valid estimates of volume changes has been shown by applying them to patients known to have lost extracellular fluid. Further confirmation that changes in haematocrit, as indices of falls in plasma volume, are valid even after surgery is provided by measurements of red cell mass, using red cells labelled with ^{99}*Tc*^{m}.

When these methods were applied to patients undergoing abdominal and non-abdominal operations, only the abdominal group showed a significant fall in plasma volume. This fall was caused not by a loss of crystalloid from the extracellular space as a whole, but by a loss of plasma; the magnitude of this loss correlated significantly with the duration of operation. These changes were also demonstrated using the radioisotope dilution indicators ^{125}*I (RISA) and* ^{131}*I (RISA).*

SINCE the 1930s there have been many studies in which fluctuations in the volumes of the body fluid compartments after major surgery have been investigated. The main interest has centred on possible changes in the extracellular volume: however, its measurement, using dilution indicators, has posed many problems.

The present study attempts to eliminate any doubts that may arise from dilution indicator techniques. It is based on the hypothesis that simultaneous measurement of haematocrit and plasma protein concentration enables a qualitative and quantitative distinction to be made between changes in the plasma compartment alone and changes in the whole extracellular space. A fall in plasma volume due to loss of plasma should cause only a rise in haematocrit, whereas a fall in plasma volume due to contraction of the whole extracellular fluid (ECF) (resulting from a loss of water and electrolytes) should cause rises both in haematocrit and in plasma protein concentration.

The hypothesis demands that in patients who are known to have lost ECF there should be parallel rises in haematocrit and plasma protein concentration and the first part of this study demonstrated this parallelism in two such groups of patients.

The second and main part of the study examined the nature of the disturbances of the body fluid compartments during the perioperative period.

Because deductions from haematocrit measurements are dependent on the constancy of the red cell mass, the third part of the study measured red cell mass changes, and compared them with direct measurements of blood loss. At the same time plasma volume changes were measured by conventional radioisotope dilution.

Patients and methods

Informed consent was obtained from the patients and the Clinical Investigations Committee of the Middlesex Hospital, and where relevant from the Isotope Advisory Panel of the DHSS.

Extracellular depletion

Simple intestinal obstruction: Fifteen patients presenting as emergencies with simple intestinal obstruction were studied. Venous blood samples were taken before and at varying intervals during resuscitation with normal saline. The haematocrit was determined in triplicate using a Hawkesley microhaematocrit centrifuge. The plasma protein concentration was measured by refractometry (Atago)—this method has been verified in the past against the biuret method (Robarts et al., 1979).

Dumping provocation tests: Ninety-three patients were given an oral glucose load (150 ml 50 per cent glucose). Peripheral blood samples were taken before ingestion and at 5, 10, 15, 20, 30, 40, 60 and 120 min afterwards. The haematocrit and plasma protein concentrations were measured as above.

Least squares regression analysis has been performed in both groups on measured plasma protein concentrations versus the value predicted from the change in haematocrit.

Estimation of plasma and extracellular volume changes

Two groups of patients were chosen.

Group 1: Intra-abdominal operations ($n = 44$)—cholecystectomy, vagotomy.

Group 2: Extra-abdominal operations ($n = 36$)—parotidectomy, thyroidectomy, mastectomy.

The anaesthetic techniques were similar in the two groups. The measured blood losses were less than 500 ml, and no blood, plasma or plasma substitutes were given to any patient. Other patient details are shown in *Table I*.

The haematocrit and plasma protein concentrations were measured immediately preoperatively, immediately postoperatively and after 4 h postoperatively.

Statistical comparisons within and between the groups have been made using Student's *t* test (paired and unpaired) for normally distributed data, and Wilkinson's rank sum test (paired and unpaired).

Table I: SUMMARY OF THE PATIENT VARIABLES IN BOTH GROUPS

	Group 1 ($n = 44$)	Group 2 ($n = 36$)
Sex	M17 F27	M14 F22
Age (yr)	51·9±13·3	49·0±14·6
Weight (kg)	66·3±13·1	68·2±10·6
Blood loss (ml)	222·0±85·6	210·3±126·9
Intravenous saline	401·6±353·9	426·7±287·8
Intravenous % theoretical ECF	2·7±2·3	2·8±1·9
Operation length (min)	85·9±31·2	109·1±26·3*

Values are mean±s.d.
* $P < 0·01$ (Wilcoxon).

Isotopic studies

Estimation of red cell mass and plasma volume changes: Two further groups of patients falling in the same categories as above were chosen. All patients were older than 25 years, and where relevant, pregnancy was excluded. Eight patients in each group had PV measurements: 10 patients in group 2 had RCM measurements. The red cell mass was measured preoperatively

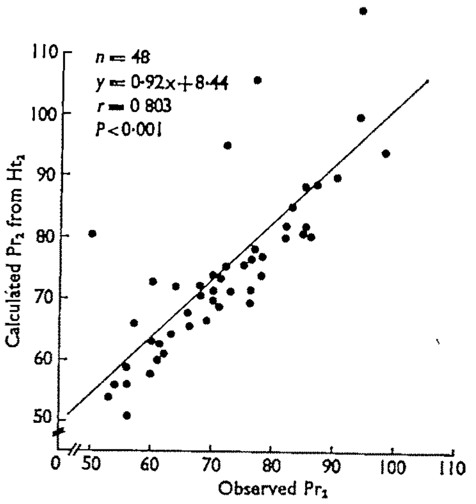

Fig. 1. Simple intestinal obstruction. Correlation between observed plasma protein concentration and that derived from the change in haematocrit (plasma protein concentrations (g/l)).

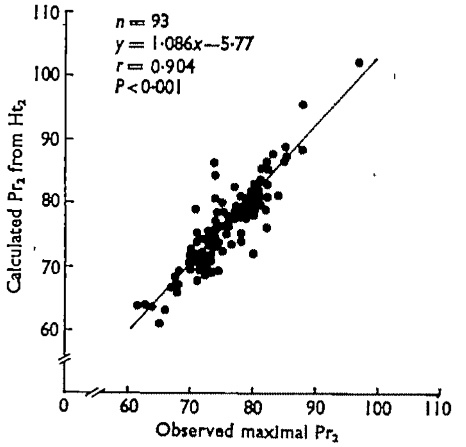

Fig. 2. Dumping provocation tests. Correlation between the observed maximal plasma protein concentration and that derived from the change in haematocrit after administration of an oral glucose load (plasma protein concentrations in g/l).

with red cells labelled with $^{99}Tc^m$ 10 μCi and postoperatively with red cells labelled with $^{99}Tc^m$ 100 μCi. The cells were labelled according to the method of Jones and Mollison (1978).

After blocking the thyroid with potassium iodide (150 mg orally 4 h before operation), the plasma volume was measured preoperatively with ^{125}I (RISA) 2 μCi and postoperatively with ^{131}I (RISA) 2 μCi. The space occupied after the operation by ^{125}I (RISA) was also measured.

Blood samples were taken through a peripheral line at 10, 15, 20 and 30 min after injection of the isotopes preoperatively. Postoperatively a sample was taken immediately before injection of the isotopes and then at 10, 15, 20 and 30 min afterwards.

The haematocrit and plasma protein concentrations were measured on each sample.

A 5-ml aliquot of saponified whole blood was counted in a J & P Counter Ratemeter MS 310 in the appropriate channels for each isotope—^{125}I and ^{131}I were counted after 48 h, by which time there were negligible counts for $^{99}Tc^m$, thus avoiding any interference from this source.

The red cell mass or plasma volume was calculated according to the formula

$$\text{RCM or PV} = \frac{\text{wt injected} \times \text{counts in 5 ml standard} \times \text{vol. standard}}{\text{wt in standard} \times \text{counts in 5 ml blood}} \times \begin{cases} \text{either } \dfrac{\text{Ht}}{100} & \text{(for RCM)} \\ \text{or } \dfrac{100-\text{Ht}}{100} & \text{(for plasma volume)} \end{cases}$$

The resulting measurements of volume were extrapolated to zero time on a semilogarithmic scale to allow for elution and decay ($^{99}Tc^m$) and extravasation (RISA).

Operative blood loss was measured by swab weighing.

All statistical comparisons were made using the Wilcoxon rank test (paired and unpaired).

Results

Extracellular depletion

Simple intestinal obstruction (*Fig.* 1): The observed plasma protein concentration in each blood sample, taken either before, during or after resuscitation, correlated very closely with the plasma protein concentration calculated from the fall in plasma volume as measured by haematocrit, i.e. crystalloid had been lost from the ECF ($r = 0{\cdot}803$, $P < 0{\cdot}001$).

Dumping provocation tests (*Fig.* 2): There was a highly significant correlation between the maximum value of plasma protein concentration and the value calculated from the haematocrit measured at the same time ($r = 0{\cdot}904$, $P < 0{\cdot}001$).

Plasma and extracellular changes after surgery

In group 1, the intra-abdominal group (*Fig.* 3), there were highly significant differences between the percentage changes in plasma volume as calculated by haematocrit and the percentage changes as calculated by plasma protein concentration. Moreover, there was a rise in haematocrit, indicating a fall in plasma volume, but no corresponding rise in plasma protein concentration. This suggests that plasma was lost from the plasma compartment, without any loss of crystalloid from the rest of the extracellular space. This loss of plasma was related to the length of operation (*Fig.* 4).

In group 2, the extra-abdominal group (*Fig.* 5), there were no significant differences between the plasma volume changes calculated from the haematocrit and those calculated from the plasma protein concentration. There was no rise in either, i.e. neither plasma nor ECF were lost, even though the length of operation in this group was significantly greater than in group 1 (*Table I*).

Isotope studies

The percentage change in red cell mass as measured by $^{99}Tc^m$-labelled red cells was compared with the change, calculated from the operative blood loss (this figure is obtained by multiplying the operative blood loss $(Ht_1 \times 0{\cdot}9)/100$ [approximate correction for whole body haematocrit] and expressing this as a percentage of the initial RCM).

There were no statistically significant differences between the changes measured by either method in either group (*Fig.* 6).

The percentage changes in plasma volume as measured before and after operation by ^{125}I (RISA) and ^{131}I (RISA) were compared in the two groups

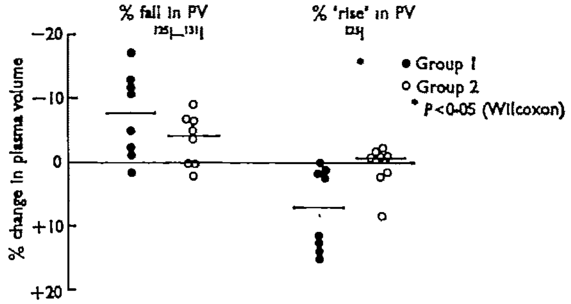

Fig. 7. The percentage changes in group 1 and group 2 in plasma volume as measured (*a*) by the difference between the volumes before and after operation as measured by ^{125}I (RISA) and ^{131}I (RISA) respectively; (*b*) by the difference in volumes occupied by the preoperative marker ^{125}I (RISA).

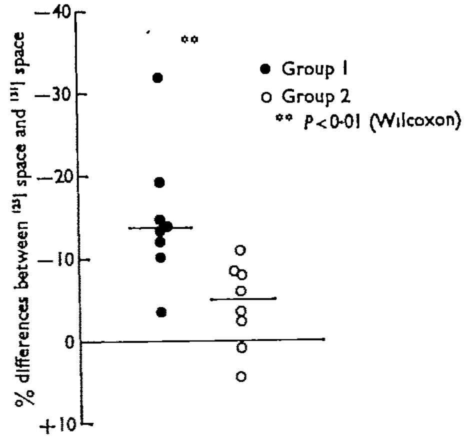

Fig. 8. A comparison of the two groups when the two volume markers (^{125}I-^{131}I and ^{125}I alone) are considered in conjunction.

after making corrections for the plasma volume fall caused by operative blood loss and for the increase in volume due to peroperative administration of intravenous crystalloid (saline) on the assumption that it is evenly distributed throughout the whole ECF (ECF calculation ♂ = 7·35 + 0·135 × BW; ♀ = 5·27 + 134 × BW [Moore et al., 1963]).
